FTT early in life, regardless of cause, is concerning because maximal postnatal brain growth occurs in the first 6 mo of life. Studies investigating the long-term sequelae of FTT in young infants and children have been conflicting, and there is no clear consensus regarding the long-term emotional, cognitive and metabolic effects. Despite inconclusive long-term outcomes in children who have FTT, investigators support early nutritional interventions for children who have poor growth. Early FTT may be associated with increased risk factors (including dyslipidemia, hypertension, and glucose intolerance) for cardiovascular disease as an adult perhaps relating to epigenetic responses to impaired nutrition and/or inflammation. The growing importance of cardiovascular disease among adults in lower and middle income nations where many children still have inadequate nutrition offers yet another reason why early FTT should be cause for concern globally.

Chapter 42

Chronic Illness in Childhood

Lisa J. Chamberlain and Paul H. Wise

EPIDEMIOLOGY

Patterns of chronic illness in childhood are complex and dynamic. Serious chronic illness in children is less common than that among adults and widely heterogeneous. These differences have profound implications for the organization of children's health services, as pediatricians have the difficult task of identifying and caring for children with unusual and varied conditions. Child health services have become far more reliant on standardized screening programs and formal systems of referral to regional specialty care programs than are health-care systems for adults. Pediatrics has been characterized by rapid progress in preventing serious acute illnesses and extending the lives of children who previously would have succumbed to their illness early in life. These factors have made the epidemiology of childhood far more dynamic than that of the adult world.

National survey data suggest that 30% of all children have some form of chronic health condition (Table 42-1). If allergies, eczema, minor visual impairments, and other conditions not likely to generate serious consequences are excluded, then between 15% and 20% of all children have a chronic physical, learning, or developmental disorder. Boys have higher rates of chronic illness than do girls. There is considerable variation in the nature and severity of chronic illnesses in children (Table 42-2). The most common serious chronic condition is asthma, with 12% of children having received a diagnosis of asthma at some time in their lives; half of these children were reported to have experienced asthma symptoms in the prior 12 mo (see Chapter 144). Mental health and behavioral conditions represent a large and growing number of children with chronic illness. It has been estimated that almost 21% of U.S. children between 9 and 17 yr of age have a diagnosable mental or addictive disorder associated with some impairment; approximately 11% had significant impairment. Estimates suggest that 5% had major depression (see Chapter 26) and approximately 9.5% have attention-deficit/hyperactivity disorder (see Chapter 33). Overweight is not usually defined as a chronic health condition, but in 2013, the American Medical Association characterized obesity as a disease. In 2010 12% of 2-5 yr olds, 18% of 6-11 yr olds, and nearly 18% of all

Table 42-1 Prevalence and Activity Limitation for Selected Chronic Diseases in Children <18 Yr of Age: United States, 2000-2003

CONDITION	NUMBER (IN THOUSANDS)	PREVALENCE (PER 100,000 CHILDREN)	ACTIVITY LIMITATION* (% OF CHILDREN WITH CONDITION)
Asthma	9,017	12,419	6.9
ADHD/ADD	4,034	6,078	5.5
Developmental delay	2,061	3,145	16.7
Congenital and other heart conditions	957	1,318	9.76

children age 12 through 19 yr have a body mass index above the 95th percentile (see Chapter 47). Comorbid conditions, such as hypertension and a variety of metabolic disorders, may exist.

The severity and impact of chronic illnesses can vary significantly. Approximately 9% of all children have activity limitations as a consequence of 1 or more chronic illnesses, which has been relatively stable since 2001. Of these children, 40% have developmental or learning disorders, 35% have chronic physical conditions, and 25% report chronic mental health disorders. Approximately 2% of children have chronic conditions and activity limitation severe enough to meet eligibility criteria for the Supplemental Security Income program. Between 12% and 18% of all children meet the chronic illness and elevated service needs of the **children with special healthcare needs (CSHCN)** definition, depending on the data set that is examined.

These current prevalence figures represent a substantial increase in childhood chronic illness in the past several decades. In 2009, approximately 9% of children were reported to have a chronic health condition that limited their activities; the comparable figure in 1960 was only 2%. Although the increase in childhood chronic illness is likely partly a result of changes in survey methodologies, improvements in diagnosis, and expanded public awareness of behavioral and developmental disorders, there is strong evidence that the prevalence of certain important chronic child health conditions has increased. Asthma rates rose from <4% in 1980 to 9.5% in 2011, with the highest rates among the poorest children. The prevalence of attention-deficit/hyperactivity disorder and autism (see Chapter 30) has also increased considerably. Although improvements in the survival of infants and young children from prematurity, congenital anomalies, and genetic disorders have also

contributed to the rising prevalence rates, this source accounts for only a small portion of all chronic illness in childhood.

Chronic illness accounts for a growing portion of child healthcare expenditures, serious illness, hospitalizations, and deaths among children in the United States. Across 37 children's hospitals, 19% of admission and 23% of inpatient charges were accounted for by only 3% of patients with frequent recurrent hospitalizations. Children with a chronic illness are hospitalized approximately 4 times more often and spend more than 7 times as many days in the hospital as children without a chronic illness. Estimates suggest that chronic illness accounts for the majority of all nontraumatic hospitalizations for children, a figure that has more than doubled in the past 4 decades, and children with chronic illnesses are experiencing increasing lengths of stay. Multiple admissions in any given year have also risen substantially: a child with a chronic condition is more likely to be readmitted, particularly for children with malignancies and neurologic conditions, although up to 25% of these may be planned admissions. The majority of all non–trauma-related deaths in children are now a result of chronic disorders. This historical shift in the distribution of pediatric hospitalization and mortality reflects not only the rise in the prevalence of childhood chronic illness, but also marked reductions in the incidence of serious acute pediatric illness.

Chronic illness is also contributing more profoundly to **social disparities** in child health. There are somewhat conflicting data on the association of poverty and the prevalence of chronic disorders in children, although most studies suggest a moderate elevation among poor children. Children enrolled in welfare cash assistance programs are more likely to have a chronic illness, and poor and African-American children have greater limitations in activity because of chronic conditions. Latino school-age children have rates of chronic illness that are similar to non-Latino whites; however, there remains little information on the prevalence and impact of chronic illness and its functional impact among the different subgroups of Latino children, as well as subgroups of Asian and Pacific Islanders.

ENHANCED NEEDS OF CHILDREN WITH CHRONIC ILLNESS AND THEIR FAMILIES

Although the nature and severity of chronic illness in children is quite heterogeneous, there are important clinical considerations that are common to virtually all such conditions regardless of their specific diagnosis or specialty group.

Financial Costs

The care required by children with serious chronic illnesses is usually associated with high financial costs. Even though the majority of children with chronic illness have coverage, 38% report being inadequately insured, experiencing gaps in coverage, and having costs or services not covered. Most states have some mechanism to facilitate health insurance coverage for children, although the nature and scope of these programs can vary considerably. A growing number of private and public health insurance plans require deductibles and copayments, which can accumulate rapidly for a child with a chronic illness. Some plans offer coverage up to a designated cost, period of hospitalization, or for a certain number of specialty visits. Once this cap has been reached, a larger portion or all of the costs may be borne by the family. This financial burden has been increasing over time, more so for families with private insurance: 20% of families have out-of-pocket expenses exceeding 10% of the family's income. The Family Opportunity Act of 2005 allows families of children with disabilities who are not financially eligible for Medicaid to buy into the program on a sliding scale. This program was created to fill the gap when children are underinsured because of private insurance limiting essential services, such as durable medical equipment and uncovered prescription drugs. The implementation of this program varies widely by state. The Patient Protection and Affordable Care Act, known colloquially as the ACA or "Obamacare," protects children with serious illness by instituting new insurance industry regulations, ending the practice of denying coverage to individuals with preexisting conditions, and allowing children to remain on their parents' insurance policies to the age of 26 yr.

Of great importance for children with serious chronic disorders, many new procedures, medications, and therapeutic regimens may be considered "experimental" by some insurers and not covered. Insurance coverage policies often generate strong incentives for hospital rather than outpatient care, even if the latter is indicated. Frequent medical visits and hospitalizations can interfere with parental employment and undermine job performance and security.

Complex Clinical Management

Children with serious chronic disorders usually require intense clinical management both in community and hospital settings. Close surveillance of disease progression, symptoms and functioning, and adverse medication effects often necessitate frequent communication and office visits. Managing hospital admissions and discharge planning may also prove complex and involve a variety of clinicians and community resources. As pressure to reduce hospitalization has grown, the burden on outpatient systems has increased accordingly. An uncoordinated approach to the multitude of required clinical visits can prove highly burdensome to the family and can undermine even the most committed family's attempts to comply. New models of care including **accountable care organizations (ACOs)** link care across the continuum, from quaternary to primary care by incentivizing multidisciplinary care teams to manage patients focusing on care coordination and prevention. The ability to capture savings through decreased admissions and emergency department use has been largely derived from the experiences of adult-focused programs; the feasibility and utility of pediatric ACOs, particularly for large populations of poor children, remain unexplored. The impact of ACOs and related financial arrangements on highly regionalized specialty service systems for children is of particular concern.

Pain

Many seriously ill children suffer from chronic pain (rheumatoid arthritis, spastic cerebral palsy), recurrent pain during exacerbations of underlying disease (inflammatory bowel diseases, sickle cell anemia), or acute pain related to procedures, surgeries, or diagnostic tests. This pain can alter a child's affect and influence their academic and social development, while also decreasing the family's quality of life (see Chapter 62). Assessing pain in young children or those with developmental disorders can be difficult and should always consider sociocultural and psychologic factors as well as developmental stage. Because serious, chronic pain is relatively unusual in children, its management may require the involvement of pediatric pain subspecialists who may practice with multidisciplinary teams in regional centers. The emotional toll on parents of children experiencing chronic pain can also be profound and require close attention by medical personnel.

Behavioral and Adjustment Issues

Although chronic illness in children elevates the likelihood that they will experience psychologic and behavioral problems, most children with chronic illness will experience the same level of psychologic and behavioral issues as other children their age. Behavioral and adjustment problems are more likely to occur the earlier the onset of the illness, particularly if it emerges in infancy. The risk of psychologic and behavioral problems does not appear to be associated with the severity of the chronic illness per se. These effects can occur across all diagnoses, although they are more profound for disorders that affect the central nervous system, including cerebral palsy, head trauma, and treatment-related complications that affect the brain, such as chemotherapy for cancer. Children with higher levels of cognitive ability appear to be less likely to develop serious behavioral or adjustment problems. Familial strife and mental illness, particularly depression in the mother, have been associated with an enhanced risk for psychologic and behavioral consequences.

Impact on Families

Like all children, a child with a chronic illness usually brings a mix of challenges and joy to a family. The presence of a chronic illness can add extra burdens, which can be expressed in a variety of forms. First,

the daily requirements of care should never be underestimated, particularly when the child is unable to perform tasks such as bathing, dressing, using the toilet, and feeding. Second, the care required by the child with chronic illness may divert needed attention from siblings and strain normal family dynamics. Third, the ultimate burden faced by families of children with a chronic illness is the emotional toll exacted by the daily struggles, pain, and, occasionally, early death that chronic illness can imply. Fourth, among the most difficult attributes of childhood chronic illness is the inherent unpredictability of its course and ultimate impact. Clinicians should be sensitive to how difficult it can be living with a child whose condition can worsen at any moment and without apparent cause. If conditions worsen to the point where medical care is futile, the evolving field of pediatric palliative care (see Chapter 43) can provide critical medical services and offer comprehensive support for grieving families. Fifth, children with serious chronic illness and their parents may harbor powerful hopes for new breakthroughs or divine intervention. Clinicians should understand the importance of these hopes for the families under their care and should explore related hopes for lesser, more incremental steps, such as attending school, playing sports, or taking a special trip.

Comprehensive Care and the Medical Home

All children require a clinician who takes responsibility for their comprehensive healthcare needs. To meet this responsibility, the coordinated implementation of a series of essential practice components, often termed the **medical home,** is recommended. These services should be provided within a broader system of care that emphasizes partnering in decision making between the family and medical providers, coordination of services among medical and community service providers, adequate health insurance coverage, ongoing screening for special healthcare needs, critical educational and community-based services, and special attention to the needs of older children as they transition to adult life and healthcare systems. Innovative new models are being suggested, including linkages between **community health centers** and academic medical partnerships, which combine the subspecialist expertise, medical technology, and inpatient care of local academic medical centers with the primary care expertise of community health centers, to create a distinctive form of ACO. Evidence suggests that the extent to which these care requirements are being met for families with children with special healthcare needs is highly variable (see Table 42-1) and thus new models are needed. Although essential for all children, these practice elements take on special importance for children with chronic disorders and are outlined as follows.

Preventive Services

Primary, preventive care is an essential component of healthcare for children with chronic disease. Although overall CSHCN use preventive medical and dental services at rates similar to those of other children, primary preventive services can easily be overlooked in addressing the more specialized needs of these patients. The most common unmet healthcare need for CSHCN is dental care. Children with chronic disorders are commonly less-well immunized than their healthy counterparts. Well child care may be disrupted by visits for acute exacerbations of the chronic disorder and clinicians should carefully evaluate whether the chronic illness or its symptoms are contraindications to immunization. A family's reliance on specialty services can be so great that the need for primary care services is overlooked. Special effort may be required to ensure the provision of high-quality primary care to children with chronic illness.

Continuity of Care

Children with chronic illnesses are particularly dependent on a stable, ongoing relationship with clinicians and the healthcare system. The duration and complexity of chronic illness in children require that the clinician responsible for coordinating the child's care have a good understanding of the child's clinical history, including patterns of exacerbation and response to medications and other interventions. Continuity of care also serves as a basis for building trust and effective communication between affected families and clinicians, a prerequisite for high-quality care. Practice structures, therefore, should ensure the identification of a principal clinical provider and facilitate the provider's involvement in all necessary care. Transitioning of care as the child reaches adulthood is also critical, but is not experienced equally across the spectrum of medical need. The greatest difficulty in transitioning care occurs in youth with more complex conditions, those with cognitive impairments, and youth from racial/ethnic minority backgrounds. The transition requires planning, coordination and recognition of the emotional bonds that likely have developed between the child (and the child's family) and the practitioner (see Chapter 112.3).

Access to Urgent Care

Clinicians should expect that children with chronic illness will have enhanced requirements for urgent consultation, emergency care, and hospitalization. Practice mechanisms that ensure rapid access to medical consultation both by telephone and office visitation are essential. Procedures for urgent referral to appropriate facilities for emergency evaluation and hospitalization should also be established. This is particularly important in managed care systems that may require primary care referral or approval for care at referral sites.

Access to Specialty Care

Children with chronic illness commonly require specialized care. The need for specialty referral is particularly important in pediatrics because serious disorders are relatively rare in children. In many countries, including the United States, there is a shortage of many pediatric subspecialists. The ACA includes provisions to encourage pediatric residents to pursue pediatric subspecialty training. Regional systems of specialty referral and hospitalization have been formalized in the past several decades, particularly for perinatal care, pediatric trauma, and children with serious chronic illness. These systems of "regionalized" specialty care have been shown to reduce dramatically morbidity and mortality among affected children. It is crucial that policymakers who develop and implement health insurance products through new marketplaces or exchanges understand the need to include access to children's hospitals and pediatric subspecialists for children with special healthcare needs. Pediatricians can play a crucial role in conveying to policymakers the special dependence of modern pediatrics on established regionalized systems of care. Regionalized care heavily relies on specialty care referrals, responsive communication between primary care practices and specialty programs is essential, particularly in conveying the reasons for referral, patient history, the nature and findings of the specialty evaluation, hospital course, and the collaborative development of a follow-up management plan.

Enhanced Information Systems

Children with chronic illness often require careful monitoring of their clinical status and the rapid evaluation of exacerbations. On-call and related coverage systems must include immediate access to up-to-date medical record information for children with complex histories and management regimens. Electronic medical records and systems that permit parent or other caretakers routine access to computerized medical record information may also prove useful. Access to current medical information, laboratory results, as well as clinical protocols and decision support algorithms could prove particularly helpful for children with complex healthcare requirements.

Linkage to Schools, Support Groups, and Community Services

Children with chronic illnesses often have special educational needs and may require the active participation of teachers and school health personnel in medical care plans. An important first step in creating a care plan is to assess the level of medical expertise available at the school site because many schools no longer have a nurse present. Special mechanisms should be established to ensure close coordination with schools, including provisions for collaborative evaluations of needs, monitoring of educational performance and social interactions, and the ongoing refinement of medical and educational management

regimens. Clinicians can prevent the isolation many families feel by connecting them to support and advocacy groups composed of other parents with similarly affected children. Such connections have been facilitated by use of the Internet, which can link children and families over wide geographic areas.

Logistic Access

The difficulties that families can experience in transporting children with serious physical or behavioral disorders should never be underestimated. Particularly for older children or those requiring wheelchairs or other equipment, urban public transportation systems may be seriously impractical. In suburban and rural areas, transportation may involve traveling over great distances. For parents who have daytime employment, extended clinic hours may be required. Many communities have implemented innovative transportation programs for families in need of health and social services, particularly when available means of travel to clinical facilities is deemed unsafe or if it requires specially equipped vehicles or the assistance of trained personnel. In a growing number of areas, a variety of forms of telemedicine have enhanced access to medical and particularly, specialty care consultation.

Cultural Sensitivity and Language Concordance

See also Chapter 4.

Clinicians must possess a basic understanding of the meaning of illness and traditions of healing in the communities they serve. Cultural competency education is a required component of pediatric residency training, empowering a new generation of pediatricians with tools needed to bridge cultural divides. Although such cultural competence of individual providers is important, access also depends on creating clinical programs that respond to local perceptions and social institutions. Cultural competence not only reduces the likelihood of misunderstandings and medical errors, but also helps ensure that clinical programs can take full advantage of the many strengths that exist in culturally defined communities.

The most basic element of communication between clinicians and families of children with a chronic illness is that they share a common language. Clinicians should not overestimate their own or a parent's basic command of a language and must ensure that conveyed information is well understood. Children should not be used as interpreters despite the fact that they often have a better command of English than do their parents. Given the complex issues chronic illness can generate, it is far more useful to integrate trained interpreters into programs for chronically ill children in locations characterized by diverse language groups.

Nondiscrimination in Access and Clinical Decision Making

Clinicians who care for children with chronic illness must recognize the power of social status to define access to care. A history of inadequate service provision or different levels of service for distinct social groups can generate deep resentment and distrust for the medical system. **Family centered care**, defined in 1987 and incorporated into The Maternal and Child Health Bureau's core objectives, includes principles that build on family strengths, honor diversity, and emphasize the centrality of community-based services among others. Many studies have suggested that even when patients have adequate health insurance, poor and minority patients are less likely to be offered recommended diagnostic and therapeutic interventions. Although the precise reasons for these observations remain unclear, it is important that provider preconceptions do not replace a careful consideration of the true desires and capabilities of families, particularly in association with new, specialized, or home-based interventions. Strategies to confront these issues include implementing a family centered care approach training and recruitment of minority health providers, educational programs for clinicians, and the active assessment of clinical decision-making and family experiences at clinical facilities.

Chapter 43

Pediatric Palliative Care

Christina Ullrich, Janet Duncan, Marsha Joselow, and Joanne Wolfe

The World Health Organization defines palliative care for children as "…the active total care of the child's body, mind and spirit, and also involves giving support to the family.…Optimally, this care begins when a life-threatening illness or condition is diagnosed and continues regardless of whether or not a child receives treatment directed at the underlying illness." Provision of palliative care applies to children with a range of acute and chronic diseases, both life-threatening and life-altering, including, but not limited to, cancer, mitochondrial disorders, cardiac disease, neurodegenerative diseases, and trauma with life-threatening sequelae (Table 43-1). In fact, medical and technological advances have resulted in children living longer, often with significant dependence on new and complex technologies. These children have complex chronic conditions across the spectrum of congenital and acquired life-threatening disorders (see Chapter 42). Children with complex chronic conditions benefit from integration of palliative care strategies. These children, who often survive near-death crises followed by the renewed need for rehabilitative and life-prolonging treatments, are best served by a system that is flexible and responsive to changing needs.

Table 43-1	Conditions Appropriate for Pediatric Palliative Care
CONDITIONS FOR WHICH CURATIVE TREATMENT IS POSSIBLE BUT MAY NOT SUCCEED	
Advanced or progressive cancer or cancer with a poor prognosis	
Complex and severe congenital or acquired heart disease	
CONDITIONS FOR WHICH THERE IS INTENSIVE LONG-TERM TREATMENT AIMED AT PROLONGING LIFE AND MAINTAINING QUALITY OF LIFE BUT PREMATURE DEATH IS STILL POSSIBLE	
Human immunodeficiency virus infection	
Cystic fibrosis	
Severe immunodeficiency	
High-risk solid-organ transplant candidates and/or recipients such as lung or multivisceral	
Chronic or severe respiratory failure	
Muscular dystrophy	
Primary pulmonary hypertension	
PROGRESSIVE CONDITIONS FOR WHICH THERE IS NO CURATIVE OPTION AND IN WHICH TREATMENT IS ALMOST EXCLUSIVELY PALLIATIVE AFTER DIAGNOSIS	
Progressive metabolic disorders (e.g. mucopolysaccharidosis, Tay Sachs)	
Batten disease	
Severe forms of osteogenesis imperfecta	
CONDITIONS INVOLVING SEVERE, NONPROGRESSIVE DISABILITY, CAUSING EXTREME VULNERABILITY TO HEALTH COMPLICATIONS	
Severe cerebral palsy with recurrent infection or difficult-to-control symptoms	
Severe neurologic sequelae of infectious disease	
Hypoxic or anoxic brain injury	
Brain malformations such as holoprosencephaly or lissencephaly	

Adapted from The Together for Short Lives (formerly the Association for Children's Palliative Care [ACT]) Life-limiting/Life-threatening Condition Categories available at http://www.togetherforshortlives.org.uk/professionals/childrens_palliative_care_essentials/approach

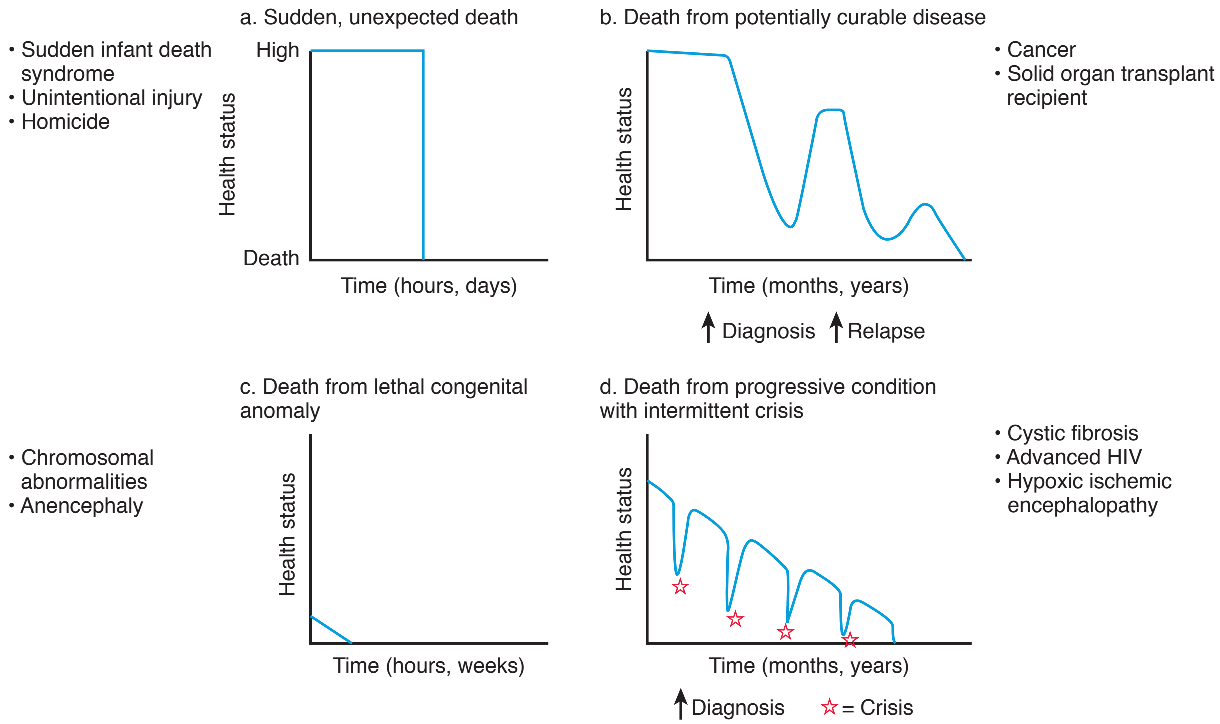

Figure 43-1 Typical illness trajectories for children with life-threatening illness. *(From Field M, Behrman R, editors:* When children die: improving palliative and end-of-life care for children and their families, *Washington, DC, 2003, National Academies Press, p. 74, Fig 3.1.)*

Although palliative care is often mistakenly understood as equivalent to end-of-life care, its scope and potential benefit extend before and well after end-of-life and is *applicable throughout the illness trajectory*. Palliative care emphasizes optimization of quality of life, communication, and symptom control, aims that may be congruent with maximal treatment aimed at sustaining life.

The mandate of the pediatrician and other pediatric clinicians to attend to children's physical, mental, and emotional health and development includes the provision of palliative care for those children who live with a significant possibility of death before adulthood (Fig. 43-1). Such comprehensive physical, psychological, social, and spiritual care requires an interdisciplinary approach. This is often possible with creative use of professional hospital and community-based providers.

In the United States, the healthcare and reimbursement structure combined with frequent use of medical technology (e.g., home ventilatory support) or continuous home nursing historically precluded formal enrollment of children on the hospice benefit when they were otherwise eligible (i.e., had an estimated prognosis of 6 mo or less). Section 2302 of the Patient Protection and Affordable Care Act, termed the **concurrent care for children requirement** eliminated the requirement that Medicaid patients <21 yr of age forgo curative or life-prolonging therapies to be eligible for hospice. Although Medicaid programs in every state are now required to provide concurrent curative/life-prolonging treatment and hospice services for hospice-eligible children, development of systems to make such concurrent care a reality has been slow. A limitation of the concurrent care for children requirement is that it does not expand access to hospice for children with life-threatening illness who do not meet hospice eligibility criteria (i.e., have a prognosis that cannot be estimated to be <6 mo). A number of state-based pediatric palliative care coalitions have formed in recent years to improve access to home-based pediatric hospice/palliative care services, using strategies such as Medicaid waivers or state plan amendments to increase coverage for hospice services. A growing number of home care agencies have also developed palliative care programs that serve as a bridge to hospice services for children not yet meeting hospice eligibility criteria. Provision of hospice or palliative care for children is often also limited by the availability of clinicians who have training or experience in caring for seriously ill children.

CARE SETTINGS

Pediatric palliative care should be provided across settings, including the hospital, outpatient settings, the home, pediatric nursing facilities, and inpatient hospice houses. **Home care** for the child with a life-threatening illness requires 24 hr per day access to experts in pediatric palliative care, a team approach, and an identified coordinator who serves as a link between hospitals, the community, and specialists and who may assist in preventing and/or arranging for hospital admissions, respite care, and increased home care support as needed. Adequate home care support and respite care, though very important, are often not readily available or families may feel using respite care is a personal failure, or they may worry that others cannot adequately care for their child's special needs.

At the end of life, children and families may need intensive support. About half of pediatric deaths occur in acute-care hospitals, and end-of-life care may thus be provided in the home, hospital, pediatric nursing facility or hospice house. Families need to feel safe and well cared for and given permission, if possible, to choose location of care. In tertiary care hospitals, most children die in the neonatal and pediatric ICUs. The philosophy of palliative care can be successfully integrated into a hospital setting, including the ICU, when the focus of care also includes the prevention or amelioration of suffering and improving comfort and quality of life. All interventions that affect the child and family need to be assessed in relationship to these goals. This proactive approach asks the question, "What can we offer that will improve the quality of this child's life and provide the most meaning and control for their family?" instead of, "What therapies are we no longer going to offer this patient?" Staff may benefit from education, support, and guidance as pediatric palliative care, like other types of intensive care, is an area of specialty. Regardless of the care setting, comprehensive palliative care requires an interdisciplinary approach that may include nurses, physicians, psychologists, psychiatrists, social workers, chaplains/clergy, child-life specialists, and trained volunteers.

PRIMARY AND SUBSPECIALTY PALLIATIVE CARE

Not all children with serious illness require care by a hospice and palliative medicine subspecialist or pediatric palliative care team. Basic palliative care knowledge, skills, and behaviors should be known to all clinicians who care for children with life-threatening illnesses and conditions. The role of the Hospice and Palliative Medicine subspecialist and team is to provide clinical consultation for more complex situations, to provide education and training, and to improve palliative care outcomes for all children and families through quality improvement and research.

COMMUNICATION, ADVANCE CARE PLANNING, AND ANTICIPATORY GUIDANCE

Although accurate prognostication is a particular challenge in pediatrics, the medical team often recognizes a terminal prognosis before the prognosis is understood by parents. This time delay may impede informed decision making about how the child lives at the end of life. Given the inherent prognostic uncertainty of a life-threatening diagnosis, discussions concerning resuscitation, symptom control, and end-of-life care planning should be initiated when the physician recognizes that a significant possibility of patient mortality exists. Having these conversations in the midst of a crisis is not ideal. Whenever possible, they should occur well in advance of the crisis or when the patient has recovered from a crisis, but is at high risk for others.

Patients and families are most comfortable being cared for by physicians and other care providers with whom they have an established relationship. Even in the face of long-standing and highly connected relationships, *clinicians often hold assumptions about parent prognostic awareness, and parent readiness and willingness to have such discussions*. In an attempt to protect families, clinicians may avoid conversations that they perceive as promoting hopelessness. However, parents greatly value honesty, and such conversations can promote parent hopefulness. A consultative palliative care team may provide the family with an opportunity to engage in sensitive conversations that are not as comfortably initiated with the primary team.

The population of children who die before reaching adulthood includes a disproportionate number of nonverbal and preverbal children who are developmentally unable to make autonomous care decisions. Although parents are usually the primary decision-makers, children should be as fully involved in discussions and decisions about their care as appropriate for their developmental status. Utilizing communication experts, child-life therapists, chaplains, social workers, psychologists, or psychiatrists to allow children to express themselves through art, play, music, talk, and writing will enhance the provider's knowledge of the child's understanding and hopes. Tools such as "Five Wishes" (for adults), "Voicing My Choices" (for adolescents), and "My Wishes" (for school-age children), have been useful in helping to gently introduce advance care planning to children, adolescents, and their families (http://www.agingwithdignity.org/index.php).

The Parents

From a parent's perspective, compassionate communication with medical providers who understand their child's illness, treatment options, and family beliefs and goals is the cornerstone of caring for children with life-threatening illness. During this period of time, one of the most significant relationships is that with the child's pediatrician, who often has an enduring relationship with the child and family, including healthy siblings. Parents need to know that their child's pediatrician will not abandon them as the goals of care evolve. A family's goals may change with the child's evolving clinical condition and other variable factors. A flexible approach rooted in ongoing communication and guidance that incorporates understanding of the family's values, goals, and religious, cultural, spiritual, and personal beliefs is of paramount importance.

Pediatricians should recognize the important role they have in continuing to care for the child and family as the primary goal of treatment may simultaneously be prolongation of life and comfort, relief of suffering, and promoting quality of life. Regular meetings between caregivers and the family are essential in order to reassess and manage symptoms, explore the impact of illness on immediate family members, and provide anticipatory guidance. At these meetings, important issues with lifelong implications for parents and their child may be discussed. Such discussions should be planned with care, ensuring that adequate time for in-depth conversation is allotted; a private, physical setting is arranged; devices silenced; and that both parents and/or others who might be identified by the family as primary supports are present. Strategies for facilitating conversations related to goals of care and decision-making are detailed below.

Families may look to their pediatrician for assurance that all treatment options have been explored. Assisting a patient's family to arrange a second opinion may be helpful. Listening to families and children speak about the future even in the face of poor prognosis may help keep the focus on living even while the child may be dying. Hoping for a miracle can coexist for parents even as they are facing and accepting the more likely reality of death.

Parents also need to know about the availability of home care, respite services, web-based support educational materials other media, and support groups. Responding to parent requests or need for counseling referrals for themselves, other children, or family is essential. Attending to the concrete needs of families such as financial, insurance and housing needs can be paramount in freeing them of worries that might interfere or compete with their ability to be fully present in their child's care.

When closer to end of life, while broaching the topic may seem daunting, exploration of how parents envision their child's death, addressing their previous loss experiences (most often with death of an adult relative) and any misconceptions they may have, is often a great relief to parents. Learning about cultural, spiritual, and family values regarding pain management, suffering, and the preferred place of end-of-life care is essential before death. Even raising thoughts about funeral arrangements, the possibility of autopsy, and organ/tissue donation can be helpful to give parents choices and know that these considerations can be discussed without fear.

A major worry of many parents is in how to involve and communicate with siblings as well as the child about the fact that most likely death is going to occur. Evidence shows that parents who have open conversations with their child about death and dying do not regret having done so. Clear communication around end-of-life issues, delivered with sensitivity and caring are directly correlated with ratings of high satisfaction with physician care. Such communication includes speaking directly to the child when appropriate. Communication is complicated by an assumed need for mutual protection in which the child wants to protect his or her parents and likewise the parents want to protect their child from painful information or sadness. Honoring the uniqueness of the child as well as understanding and respecting the family's communication style, values, spirituality, and culture, is critical in these highly sensitive conversations.

In communications with the child and family, the physician should avoid giving specific estimates of survival length, even when the child or family explicitly asks for them. These predictions are invariably inaccurate because population-based statistics do not predict the course for individual patients. A more honest approach may be to *explore ranges of time in general terms* ("weeks to months," "months to years"). The physician can also ask parents what they might do differently if they knew how long their child would live and then assist them in thinking through the options relating to their specific concerns (suggest celebrating upcoming holidays/important events earlier in order to take advantage of times when the child may be feeling better). It is generally wise to suggest that relatives who wish to visit might do so earlier rather than later, given the unpredictable trajectory of many conditions.

For the child and family, the integration of bad news is a process, not an event, and when done sensitively does not take away hope or alter the relationship between the family and physician. The physician should expect that some issues previously discussed may not be fully resolved for the child and parents (do-not-resuscitate [DNR] orders, artificial nutrition or hydration) and may need to be revisited over

time. Parents of a child with chronic illness may reject the reality of an impending death because past predictions may not have been accurate. Whether they are parents of a child with a chronic illness or of a child whose death is the result of accident or sudden catastrophic illness, they may experience great anxiety, guilt, or despair.

The Child

Truthful communication that takes into account the child's developmental stage and unique lived experience can help to address the fear and anxiety commonly experienced among children with life-threatening illness. Responding in a developmentally appropriate fashion (Table 43-2) to a child's questions about death, such as "What's happening to me?" or "Am I dying?" requires a careful exploration of what is already known by the child, what is really being asked (the question behind the question), and why the question is being asked at this particular time and in this setting. It may signal a need to be with someone who is comfortable listening to such unanswerable questions. Many children find nonverbal expression much easier than talking; art, play therapy, and storytelling may be more helpful than direct conversation.

A child's perception of death depends on the child's conceptual understanding of *universality* (that all things inevitably die), *irreversibility* (that dead people cannot come back to life), *nonfunctionality* (that being dead means that all biologic functions cease), and *causality* (that there are objective causes of death).

Very young children may struggle with the concepts of irreversibility and nonfunctionality. For young, school-age children, who are beginning to understand the finality of death, worries may include magical thinking in which their thoughts, wishes, or bad behavior might be the underlying cause for their illness. Older children seek more factual information to gain some control over the situation.

Table 43-2 Developmental Questions, Thoughts, and Concepts of Dying and with Responsive Strategies

TYPICAL QUESTIONS AND STATEMENTS ABOUT DYING	THOUGHTS THAT GUIDE BEHAVIOR	DEVELOPMENTAL UNDERSTANDING OF DEATH	STRATEGIES AND RESPONSES
MONTHS-3 YR			
"Mommy, don't cry." *"Daddy, will you still tickle me when I'm dead?"*	Limited understanding of events, future and past, and of the difference between living and nonliving.	May have "sense" that something is wrong. Death is often viewed as continuous with life (analogous to being awake and being asleep).	Optimize comfort, and consistency; familiar persons, objects, routines. Use soothing songs, words, and touch. *"I will always love you."* *"I will always take care of you."* *"I will tickle you forever."*
3-5 YR			
"I did something bad and so I will die." *"Can I eat anything I want in heaven?"*	Concepts are simple and reversible. Variations between reality and fantasy.	The child may see death as temporary and reversible, and not universal. May feel responsible for illness. Death may be perceived as an external force that can get you.	Assure child that illness is not the child's fault. Provide consistent caregivers. Promote honest simple language. Use books to explain the life cycle and promote questions and answers. *"You did not do anything to cause this."* *"You are so special to us and we will always love you."* *"We know (God, Jesus, Grandma, Grandpa) are waiting to see you."*
5-10 YR			
"How will I die?" *"Will it hurt?"* *"Is dying scary?"*	The child begins to demonstrate organized, logical thought. Thinking becomes less esoteric. The child begins to problem solve concretely, reason logically, and organize thoughts coherently. However, the child has limited abstract reasoning.	The child begins to understand death as real and permanent. Death means that your heart stops, your blood does not circulate, and you do not breathe. It may be viewed as a violent event. The child may not accept death could happen to himself or herself or anyone the child knows, but starts to realize that people the child knows will die.	Be honest and provide specific details if they are requested. Help and support the child's need for control. Permit and encourage the child's participation in decision making. *"We will work together to help you feel comfortable. It is very important that you let us know how you are feeling and what you need. We will always be with you so that you do not need to be afraid."*
10-18 YR			
"I'm afraid if I die my mom will just break down." *"I'm too young to die. I want to get married and have children."* *"Why is God letting this happen?"*	Abstract thoughts and logic possible. Body image is important. Need peer relationships for support and for validation. Altruistic values • staying alive for family • parents, siblings • donating organs/tissue Disbelief that he/she is dying.	Understand death as irreversible, inevitable and universal. Needs reassurance of continued care and love. Search for meaning and purpose of life.	Reinforce child/adolescent's self-esteem, sense of worth, and self-respect. Allow need for privacy, independence, access to friends and peers. Tolerate expression of strong emotions and permit participation in decision making. *"I can't imagine how you must be feeling. Despite it all, you are doing an incredible job. I wonder how I can help?"* *"What's most important to you now?"* *"What are your hopes…your worries?"* *"You have taught me so much, I will always remember you."*

Adapted from Hurwitz C, Duncan J, Wolfe J: Caring for the child with cancer at the close of life, *JAMA* 292:2141-2149, 2003.

Children's fears of death are often centered on the concrete fear of being separated from parents and other loved ones and what will happen to their parents rather than themselves. This can be true for teens and young adults as well. This fear may be responded to in different ways: some families may give reassurance that loving relatives will be waiting, while others use religious figures to refer to an eternal spiritual connection.

Even though adolescents may have a conceptual understanding of death similar to that of adults, working with the adolescent with life-threatening illness presents unique concerns and issues. The developmental work of adolescence includes separating from their parents, developing strong peer relationships, and moving towards independent adulthood. For this particular population, the teenager's developmental need to separate is complicated by the often increasing dependence both physically and emotionally on the teenager's parents. At the same time, adolescents are often asked to be part of the decision-making process without always having the emotional experience to fully understand the impact.

In addition to developmental considerations, understanding related to the child's life experiences, the length of the child's illness, the understanding of the nature and prognosis of the illness, the child's role in the family (peacemaker, clown, troublemaker, the "good" child) should be considered in communication with children.

Parents have an instinctive and strong desire to protect their children from harm. When facing the death of their child, many parents attempt to keep the reality of impending death hidden from their child with the hope that the child can be "protected" from the harsh reality. Although it is important to respect parental wishes, it is also true that most children already have a sense of what is happening to their bodies even when it has been purposely left unspoken. Children may blame themselves for their illness and the hardships that it causes for their loved ones. Perpetuating the myth that "everything is going to be all right" takes away the chance to explore fears and provide reassurance. Honest communication also allows opportunities for memory and legacy making and saying goodbye.

School is the "work" of childhood and is important in optimizing quality of life for a child seeking "normalcy" in the face of illness. Finding ways to help children and their families to maintain these connections through modification of the school day and exploring options to promote educational and social connections into the home or into the hospital room can be meaningful in the event that a child is not well enough to attend school. Video conferencing can readily be arranged from almost any setting. As with the younger child, finding ways to help the adolescent maintain peer relationships and school based programming can be important in maximizing quality of life.

The Siblings

Brothers and sisters are at special risk both during their sibling's illness and after the death. Because of the extraordinary demands placed on parents to meet the needs of their ill child and their own needs, healthy siblings may feel that their own needs are not being acknowledged or fulfilled. These feelings of neglect may then trigger guilt about their own good health and resentment toward their parents and ill sibling. Younger siblings may react to the stress by becoming seemingly oblivious to the turmoil around them. Some younger siblings may feel guilty as a result of "wishing" the affected child would die so they could get their parents back; preschool children may believe that their wishes caused the death of their sibling ("magical thinking"; see Chapter 7). Parents need to know that these are normal responses, and siblings should be encouraged to maintain the typical routines of daily living. Siblings who are most involved with their sick brothers or sisters before death usually adjust better both at the time of and after the death. Acknowledging and validating sibling feelings, being honest and open, and appropriately involving them in the life of their sick sibling provide a good foundation for the grief process. It is often helpful to identify a person in the family (such as a loving aunt) or school (such as a counselor) to offer confidential and supportive opportunities for the sibling to reflect on their family experience.

The Staff

Adequate support for the staff providing palliative care is necessary to prevent depression, emotional withdrawal, and/or other symptoms. Offering educational opportunities and emotional support for staff at various stages of caring for a child with life-threatening illness can be helpful in bettering patient/family care and preventing staff from experiencing compassion fatigue, burn out and long-term repercussions, including the possibility of leaving the field.

Goals of Care and Decision Making

In the course of a child's life-limiting illness, a series of important decisions may arise in relation to location of care, medications with risks and benefits, not starting and or discontinuing life-prolonging treatments, experimental treatments in research protocols, and the use of integrative therapies (see Chapters 3 and 64). Such family decisions are greatly facilitated by opportunities for in-depth and guided discussions around **goals of care** for their child. This is often accomplished by eliciting parent (and child) understanding of the child's condition and asking open-ended questions that explore the parent's and child's hopes, worries, and family values. Goals of care conversations include what is most important for them as a family, considerations of their child's clinical condition, and their values and beliefs, including cultural, religious, and spiritual considerations. Table 43-3 lists specific questions that can effectively guide these discussions. The conversation should also include a review of previous discussions, active listening to concerns and issues as they are raised, opportunities to repeat back elements of the discussion to ensure clarity, and provision of honest, factual answers even in areas of uncertainty.

Decision making should be focused on the goals of care, as opposed to limitations of care; "This is what we can offer" instead of "There is nothing more we can do." Instead of meeting specifically to discuss "withdrawing support" or a DNR order, a more general discussion centered on the goals of care will naturally lead to considering which interventions are in the **child's best interests and can present an opportunity for the clinicians to make recommendations based on these goals.** By offering medical recommendations based on family goals and the clinical reality, the team can decrease the burden of responsibility for decision making that parents carry.

Resuscitation Status

The legal mandate requiring attempted resuscitation for cardiorespiratory arrest unless a written DNR order is in place is a complex and confusing concept for many parents. In broaching this topic, rather than asking parents if they want to forgo cardiopulmonary resuscitation for their child (and placing the full burden of decision making on them), it is preferable to discuss whether or not resuscitative interventions are likely to benefit the child. *It is important to make recommendations based on overall goals of care and medical knowledge of potential benefit and/or harm of these interventions*. Once the goals of therapy are agreed upon, the physician is required to write a formal order. Out-of-hospital DNR verification forms are available in many states, which, if completed on behalf of the child, affirm that rather than initiating resuscitative efforts, emergency response teams are obligated to provide comfort measures when called to the scene. Some states have implemented the **physician orders for life-sustaining treatment (POLST)** system. A POLST order is completed for children with life-threatening illness, translating the expressed wishes of the parents (and

Table 43-3	Five Basic Questions to Guide Goals of Care Conversation
Tell us about your child as a person; what does your child enjoy? What is your understanding of your child's illness/condition? In light of your understanding, what is most important to you regarding your child's care? What are you hoping for? What are your worries? In the face of your child's illness/condition, what gives you strength?	

in some cases, of the child) into actionable orders (www.polst.org). It may also be beneficial to write a letter delineating decisions regarding resuscitation interventions and supportive care measures to be undertaken for the child, particularly if POLST are not available. The letter should be as detailed as possible, including recommendations for comfort medications and contact information for caregivers best known to the patient. Such a letter, given to the parents, with copies to involved caregivers and institutions, can be a useful communication aid, especially in times of crisis. If a child may die in the home setting, and the parents opt to use on out-of-hospital DNR verification form or POLST, plans to pronounce the child and provide support for the family must be in place. If the child has been referred to hospice, the hospice personnel usually fulfill those responsibilities.

Conflicts in decision making can occur within families, within healthcare teams, between the child and family, and between the family and professional caregivers. For children who are developmentally unable to provide guidance in decision making (neonates, very young children, or children with cognitive impairment), parents and healthcare professionals may come to different conclusions as to what is in the child's best interests. Given the shifting boundary that separates childhood from adulthood, decision making around the care of adolescents presents specific challenges. In some families and cultures, truth telling and autonomy are secondary to maintaining the integrity of the family. (see Chapter 4). Although frequently encountered, differences in opinion are often manageable for all involved when lines of communication are kept open, team and family meetings are held, and the goals of care are clear.

Symptom Management

Intensive symptom management is another cornerstone of pediatric palliative care. Alleviation of symptoms reduces suffering of the child and family, and allows them to focus on other concerns and participate in meaningful experiences. Despite increasing attention to symptoms, and pharmacologic and technical advances in medicine, children often suffer from multiple symptoms. Table 43-4 lists key elements and general approaches to managing symptoms.

Pain is a complex sensation triggered by actual or potential tissue damage and influenced by cognitive, behavioral, emotional, social, and cultural factors. Effective pain relief is essential to prevent central sensitization, a central hyperexcitation response that may lead to escalating pain, and to diminish a stress response that may have a variety of physiologic effects. Assessment tools include self-report tools for children who are able to communicate their pain verbally, as well as tools based on behavioral cues for children who are unable to do so because of developmental delays, medical conditions or cognitive limitations. Tables 43-5 to 43-7 address management of pain (see Chapter 62).

Table 43-4	Key Elements of Effective Symptom Management

Establish and periodically revisit goals of care and ensure that goals are communicated to entire care team.
Anticipate and plan for symptoms before they occur.
Assess the child for symptoms regularly, using consistent and developmentally appropriate assessment tools.
- Utilize self-report, if the child is able to reliably report symptoms.
- Evaluate all aspects of the symptom, including quality, frequency, duration, and intensity.

Consider the holistic nature of symptoms.
- Explore the meaning that symptoms may have for families in their social, cultural, religious context.
- Assess distress caused by the symptom.
- Evaluate the degree of functional impairment from the symptom.

Understand the pathophysiology of the symptom and establish a complete differential diagnosis.
Treat the underlying cause if possible, weighing benefits and risks, in the context of goals of care.
Choose the least-invasive route for medications—by mouth whenever possible.
Prescribe regular medications for constant symptoms, and consider prn doses for breakthrough or uncontrolled symptoms.
Consider both pharmacologic and nonpharmacologic approaches.
Reassess the symptom and response to interventions regularly.
- For refractory symptoms, revisit the differential diagnosis and review potentially contributing factors.
- Effective interventions relieve the symptom and reduce distress and functional impairment.

Partner with families to identify and address any barriers to optimal control of symptoms.
Address spiritual, emotional, and existential suffering in addition to physical suffering as these are often interrelated.

Table 43-5	Guidelines for Pain Management

Utilize nonopioid analgesics as monotherapy for mild pain and together with opioids for more severe pain.
- Nonopioid analgesics include acetaminophen, nonsteroidal antiinflammatory drugs (NSAIDs), salicylates, and selective cyclooxygenase (COX-2) inhibitors.

For moderate or severe pain, start with a short-acting opioid at regular intervals.
- When dose requirements have stabilized, consider converting opioid to a long-acting formulation with doses available for breakthrough or uncontrolled pain, as needed.
- For uncontrolled pain, increase opioid dose by 30-50%; for severe pain increase by 50-100%.
- Avoid codeine and opioids with mixed agonist activity (e.g., butorphanol, pentazocine).

Administer medications via the simplest, most effective, and least-distressing route.
Dispel the myth that strong medications should be saved for extreme situations or the very end of life.
- Opioids do not have a "ceiling effect," and escalating symptoms may be treated with an increase in dose.

Clarify for families the differences between tolerance, physical dependence, and addiction.
Anticipate and treat/prevent common analgesic side effects (gastritis with NSAIDs; constipation, pruritus, nausea, sedation with opioids).
- Always initiate a bowel regimen to prevent constipation when starting opioids.
- Consider a stimulant for opioid-induced somnolence.
- Pruritus rarely indicates a true allergy. If not responsive to an antihistamine, consider low-dose naloxone or switching opioids.
- Consider switching to a different opioid for intolerable side effects or neurotoxicity (e.g., myoclonus).
- Use an equianalgesic conversion table when switching opioids, and account for incomplete cross-tolerance.

Consider the use of adjuvant drugs for specific pain syndromes, and for their opioid-sparing effect:
- Antidepressants (e.g., amitriptyline, nortriptyline) and anticonvulsants (e.g., gabapentin, carbamazepine, topiramate) for neuropathic pain.
- Steroids or NSAIDs for bone pain.
- Sedatives and hypnotics for anxiety and muscle spasm.
- To enhance analgesia from opioids, consider clonidine or ketamine.
  - Use topical local anesthetics (lidocaine, prilocaine, bupivacaine) when possible.
  - Consider anesthetic blocks for regional pain.
  - Consider palliative radiation therapy.
  - Consider psychological approaches (e.g., cognitive or behavioral therapy) and integrative therapies (e.g., acupuncture, massage).

Table 43-6 Pharmacologic Approach to Symptoms Commonly Experienced by Children with Life-Threatening Illness

SYMPTOM	MEDICATION	STARTING DOSE	COMMENTS
Pain—mild	Acetaminophen	15 mg/kg po q 4 hr, max 4 g/day	Available po (including liquid), pr, IV
	Ibuprofen	10 mg/kg po q 6 hr	PO (including liquid) only; avoid if risk of bleeding; use only in infants ≥6 mo. Use with caution in congestive heart failure. Chewable tablets contain phenylalanine
	Trilisate	10-15 mg/kg po tid	Trilisate may have less antiplatelet activity and therefore pose less risk for bleeding than other salicylates. Salicylates, however, have been associated with Reye syndrome in children <2 yr
Pain—moderate/severe	Morphine immediate release (i.e., MSIR)	0.3 mg/kg po q 4 hr if <50 kg; 5-10 mg po q 4 hr[*,†]	Also available in IV/SQ formulation[‡,§]
	Oxycodone	0.1 mg/kg po q 4 hr if <50 kg; 5-10 mg po q 4 hr if >50 kg[*,†]	No injectable formulation[‡,§]
	Hydromorphone	0.05 mg/kg po q 4 hr if <50 kg; 1-2 mg po q 4 hr if >50 kg[*,†]	Also available in IV/SQ formulation. Injectable form very concentrated, facilitating subcutaneous delivery[‡,§]
	Fentanyl	0.5-1.5 μg/kg IV/SQ q 30 min[*,†]	Rapid infusion may cause chest wall rigidity[‡,§]
	Methadone	Starting dose 0.1-0.2 mg/kg po bid. May give tid if needed. Recommend consultation with experienced clinician for equivalence dosing from other opioids.[*,†]	Only opioid with immediate and prolonged effect available as a liquid; do not adjust dose more often than every 72 hr as prolonged biologic half-life > than therapeutic half-life. Knowledge of the pharmacokinetics of methadone is needed for converting to and from doses of other opioids. Also available IV/SQ. May cause QT interval prolongation (consider ECG), especially in adults on >200 mg/day or in those at risk for QT prolongation. Interacts with several antiretrovirals[§]
Pain—sustained release	MS Contin Kadian (contains sustained-release pellets), Avinza (contains immediate and extended release beads)	Total daily dose of MSIR divided bid-tid	Do not crush MS Contin. For those unable to swallow pills, Kadian and Avinza capsules may be opened and contents mixed with food but *cannot be chewed*. Kadian contents may be mixed in 10 mL water and given via 16-French G-tube. Avoid alcohol with Avinza. Larger dose formulation may not be suitable for small children[§]
	Oramorph		
	OxyContin	Total daily dose of oxycodone divided bid-tid	Do not crush[§]
	Transdermal fentanyl patch	Divide 24-hr po morphine dose by 2 to determine starting dose of transdermal fentanyl. There is no data on the equianalgesic conversion from transdermal fentanyl to any oral opioid	Smallest patch size may be too high for small children. For children >2 yr. Apply to upper back in young children. Patch may not be cut. Typically for patients on at least 60 mg morphine/day or its equivalent. Not appropriate when dosage changes are frequent or for opioid-naïve patients. Fever >40°C results in higher serum concentrations[§]
Pain—neuropathic	Nortriptyline	0.5 mg/kg po at bedtime to maximum of 150 mg/day	Fewer anticholinergic side effects than amitriptyline. May cause constipation, sedation, postural hypotension, dry mouth. May cause QT interval prolongation (consider ECG). At higher doses monitor ECG and plasma levels
	Gabapentin	Start at 5 mg/kg/day at bedtime and gradually increase to 10-15 mg/kg/day divided tid; titrate up by 5 mg/kg/day every 3-4 days as needed but not to exceed 50-75 mg/kg/day (3600 mg/day)	May cause neuropsychiatric events in children (aggression, emotional lability, hyperkinesia), usually mild but may require discontinuation of gabapentin. May cause dizziness, drowsiness, tremor, nystagmus, ataxia, swelling
	Pregabalin	Start at 1 mg/kg/dose po at bedtime for 3 days, then increase to 1 mg/kg/dose bid. Increase every 3 days to 3 mg/kg/dose po bid (maximum: 6 mg/kg/dose)	
	Methadone	See previous listing	See previous listing
Dyspnea	Morphine, immediate release (i.e., MSIR)	0.1 mg/kg po q 4 hr prn[*,†]	All opioids may relieve dyspnea. For dyspnea, the starting dose is 30% of the dose that would be administered for pain[§]
	Lorazepam	0.025-0.05 mg/kg IV/po q 6 hr, up to 2 mg/dose	See previous listing

Table 43-6 Pharmacologic Approach to Symptoms Commonly Experienced by Children with Life-Threatening Illness—cont'd

SYMPTOM	MEDICATION	STARTING DOSE	COMMENTS
Respiratory secretions	Scopolamine patch	1.5 mg patch, change q 72 hr	Excessive drying of secretions can cause mucus plugging of airways. Good for motion-induced nausea and vomiting. Handling patch and contacting eye may cause anisocoria and blurry vision. May fold patches but do not cut them. Anticholinergic side effects possible
	Glycopyrrolate	0.04-0.1 mg/kg po q 4-8 hr	Powerful antisialagogue. Excessive drying of secretions can cause mucus plugging of airways. Anticholinergic side effects possible. Quaternary ammonium structure limits its ability to cross lipid membranes, such as the blood–brain barrier (in contrast to atropine, scopolamine and hyoscyamine sulfate), so may exert fewer central anticholinergic effects
	Hyoscyamine sulfate	4 gtt po q 4 hr prn if <2 yr; 8 gtt po q 4 hr prn if 2-12 yr; do not exceed 24 gtt/24 hr	Anticholinergic side effects possible, including sedation. May be given sublingually
	Atropine	1-2 gtt SL q 4-6 hr prn	Give 0.5% ophthalmic drops sublingually
Nausea	Metoclopramide	0.1-0.2 mg/kg/dose q 6 hr, up to 10 mg/dose (prokinetic and mild nausea dosing). For chemotherapy-associated nausea 0.5-1 mg/kg q 6 hr prn po/IV/SC, give with diphenhydramine and continue diphenhydramine for 24 hr after last dose of high-dose metoclopramide to prevent extrapyramidal reaction	Helpful when dysmotility is an issue; may cause extrapyramidal reactions, particularly in children following IV administration of high doses. Contraindicated in complete bowel obstruction or pheochromocytoma
	Ondansetron	0.15 mg/kg dose IV/po q 8 hr prn. No single intravenous dose should exceed 16 mg because of risk of QT prolongation	Significant experience in pediatrics. Good empiric therapy for nausea in palliative care population. Oral dissolving tablet contains phenylalanine. Higher doses used with chemotherapy although single 32 mg IV dose is no longer available (risk for QT prolongation). Consider ECG monitoring in patients with electrolyte abnormalities, congestive heart failure, bradyarrhythmias, or in patients on other medications with the potential to cause QT prolongation
	Dexamethasone	0.1 mg/kg/dose tid po/IV; max dose 10 mg/day	Also helpful with hepatic capsular distention, bowel wall edema, anorexia, increased intracranial pressure. May cause mood swings or psychosis
	Lorazepam	See previous listing	See previous listing
	Dronabinol	2.5-5 mg/m^2/dose q 3-4 hr	Available in 2.5- and 5-mg capsules. May remove liquid contents from capsules for children who cannot swallow capsules. Avoid in patients with sesame oil hypersensitivity or history of schizophrenia. May cause euphoria, dysphoria or other mood changes. Tolerance to central nervous system side effects usually develops in 1-3 days of continuous use. Avoid in patients with depression or mania
	Scopolamine patch	See previous listing	See previous listing
Anxiety	Lorazepam	See previous listing	See previous listing
Agitation	Haloperidol	0.01 mg/kg po tid prn for acute onset: 0.025-0.050 mg/kg po, may repeat 0.025 mg/kg in 1 hr prn	May cause extrapyramidal reactions, which can be reversed with diphenhydramine or Cogentin. Safety not established in children <3 yr
Sleep disturbance/ insomnia	Lorazepam	See previous listing	See previous listing
	Trazodone	Children 6-18 yr: 0.75-1 mg/kg/dose, given bid-tid if needed If >18 yr, start at 25-50 mg/dose, given bid-tid if needed	Potentially arrhythmogenic
Fatigue	Methylphenidate	0.3 mg/kg/dose titrated as needed, up to 60 mg/day	Rapid antidepressant effect; also improves cognition. Administer before meals to avoid appetite suppression. Use with caution in children at risk for cardiac arrhythmia. Available as liquid and chewable tablet

Continued

Table 43-6 Pharmacologic Approach to Symptoms Commonly Experienced by Children with Life-Threatening Illness—cont'd

SYMPTOM	MEDICATION	STARTING DOSE	COMMENTS
Pruritus	Diphenhydramine	0.5-1 mg/kg q 6 hr IV/po (100 mg max per day)	May reverse phenothiazine-induced dystonic reactions. Topical formulation on large areas of the skin or open area may cause toxic reactions. May cause paradoxical reaction in young children
	Hydroxyzine	0.5-1 mg/kg q 6 hr IV/po (600 mg maximum per day)	
Constipation	Docusate	40-150 mg/day po in 1-4 divided doses	Stool softener available as liquid or capsule
	MiraLAX	<5 yr: ½ scoop (8.5 g) in 4 oz of water daily >5 yr: 1 scoop (17 g) in 8 oz of water daily	Tasteless powder may be mixed in beverage of choice. Now available nonprescription
	Lactulose	5-10 mL po up to q 2 hr until bowel movement	Bowel stimulant; dosing q 2 hr may cause cramping
	Senna	2.5 mL po daily (for children weighing >27 kg)	Bowel stimulant; available as granules
	Dulcolax	3-12 yr: 5-10 mg po daily >12 yr 5-15 mg po daily	Available in oral or rectal formulation
	Pediatric Fleets Enema	2.5 oz pediatric enema for children 2-11 yr; adult enema for children ≥12 yr	May repeat ×1 if needed. Do not use in neutropenic patients
	Methylnaltrexone	10-20 kg: 2 mg SC 21-33 kg: 4 mg SC 34-46 kg: 6 mg SC 47-62 kg: 8 mg SC 63-114 kg: 12 mg SC ≥155 kg: 0.15 mg/kg SC Administer 1 dose every other day as needed; maximum of 1 dose per 24 hr	A peripherally acting opioid antagonist for opioid-induced constipation. Usually works within 30-60 minutes of administration
Muscle spasm	Diazepam	0.5 mg/kg/dose IV/po q 6 hr prn; initial dose for children <5 yr is 5 mg dose; for children ≥5 yr dose is 10 mg/dose	May be irritating if given by peripheral IV
	Baclofen	5 mg po tid, increase by 5 mg/dose as needed	Helpful with neuropathic pain and spasticity; abrupt withdrawal may result in hallucinations and seizures; not for children <10 yr
Seizures	Lorazepam	0.1 mg/kg IV/po/SL/PR; repeat q 10 min ×2	
	Diazepam	0.1 mg/kg q 6 hr (max 5 mg/dose if <5 yr; max 10 mg/dose if >5 yr)	May be given pr as Diastat (0.2 mg/kg/dose q 15 minutes ×3 doses)
Neuroirritability	Gabapentin	See previous listing	
	Clonidine	Starting dose: 0.05 mg/day. May increase every 3-5 days by 0.05 mg/day to 3-5 µg/kg/day given in divided doses 3-4 times/day; maximum dose is 0.3 mg/day May switch from oral to transdermal route once optimal oral dose is established; Transdermal dose is equivalent to the total oral daily dose (e.g., if total oral dose is 0.1 mg/day, apply 1 patch (delivers 0.1 mg/day). Change patch every 7 days.	Transdermal patch may contain metal (e.g., aluminum) that may cause burns if worn during MRI scan. Remove patch prior to MRI. Patch may be cut into quarter or half fractions based on dose needed
	Clonazepam	<10 yr or <30 kg Initial dose: 0.01-0.03 mg/kg/day divided tid; ≥10 yr (≥30 kg) Initial dose: up to 0.25 mg po tid; may increase by 0.5-1 mg/day every 3 days Maintenance dose: 0.05-0.2 mg/kg/day up to 20 mg/day	
Anorexia	Megestrol acetate	10 mg/kg/day in 1-4 divided doses, may titrate up to 15 mg/kg/day or 800 mg/day	For children >10 yr. Acute adrenal insufficiency may occur with abrupt withdrawal after long-term use. Use with caution in patients with diabetes mellitus or history of thromboembolism. May cause photosensitivity
	Dronabinol	See previous listing	See previous listing
	Cyproheptadine	Children ≥2 yr and adolescents: 0.08 mg/kg po q 8 hr; if no benefit in 5 days, increase dose by 0.04-0.08 mg/kg/dose maximum daily dose: ≤6 yr: 12 mg/day; 7-14 yr: 16 mg/day; ≥15 yr: 32 mg/day	Potent antihistamine and serotonin antagonist

*Infants <6 mo should receive 25-30% of the usual opioid starting dose.

†Although the usual opioid starting dose is presented, dose may be titrated as needed. There is no ceiling/maximum dose for opioids.

‡Breakthrough dose is 10% of 24 hr dose. See Chapter 62 for information regarding titration of opioids.

§Side effects from opioids include constipation, respiratory depression, pruritus, nausea, urinary retention, physical dependence.

ECG, electrocardiogram; gtt, drops; hr, hr; IV, intravenously; po, by mouth; pr, rectally; prn, as needed; SC, subcutaneously; SL, sublingually.

Adapted from Ullrich C, Wolfe J: Pediatric pain and symptom control. In Walsh TD, Caraceni AT, Fainsinger R, et al: *Palliative medicine*, Philadelphia, 2008, Saunders, pp. 1101-1102, Table 198.3.

Table 43-7 Nonpharmacologic Approach to Symptoms Commonly Experienced by Children with Life-Threatening Illness

SYMPTOM	APPROACH TO MANAGEMENT
Pain	Prevent pain when possible by limiting unnecessary painful procedures, providing sedation, and giving pre-emptive analgesia prior to a procedure (e.g., including sucrose for procedures in neonates) Address coincident depression, anxiety, sense of fear or lack of control Consider guided imagery, relaxation, hypnosis, art/pet/play therapy, acupuncture/acupressure, biofeedback, massage, heat/cold, yoga, transcutaneous electric nerve stimulation, distraction
Dyspnea or air hunger	Suction secretions if present, positioning, comfortable loose clothing, fan to provide cool, blowing air Limit volume of IV fluids, consider diuretics if fluid overload/pulmonary edema present Behavioral strategies including breathing exercises, guided imagery, relaxation, music, distraction
Fatigue	Sleep hygiene (establish a routine, promote habits for restorative sleep) Regular, gentle exercise; Prioritize or modify activities Address potentially contributing factors (e.g., anemia, depression, side effects of medications) Aromatherapy*: peppermint, rosemary, basil
Nausea/vomiting	Consider dietary modifications (bland, soft, adjust timing/volume of foods or feeds) Aromatherapy*: ginger, peppermint, lavender acupuncture/acupressure
Constipation	Increase fiber in diet, encourage fluids, ambulation (if possible)
Oral lesions/dysphagia	Oral hygiene and appropriate liquid, solid and oral medication formulation (texture, taste, fluidity). Treat infections, complications (mucositis, pharyngitis, dental abscess, esophagitis) Oropharyngeal motility study and speech (feeding team) consultation
Anorexia/cachexia	Manage treatable lesions causing oral pain, dysphagia, or anorexia. Support caloric intake during phase of illness when anorexia is reversible. Acknowledge that anorexia/cachexia is intrinsic to the dying process and may not be reversible Prevent/treat coexisting constipation
Pruritus	Moisturize skin Trim child's nails to prevent excoriation Try specialized antiitch lotions Apply cold packs Counterstimulation, distraction, relaxation
Diarrhea	Evaluate/treat if due to obstipation Assess and treat infection Dietary modification
Depression	Psychotherapy, behavioral techniques, setting attainable daily goals Aromatherapy*: bergamot, lavender
Anxiety	Psychotherapy (individual and family), behavioral techniques Aromatherapy*: clary sage, angelica, mandarin, lavender
Agitation/terminal restlessness	Evaluate for organic or drug causes Educate family Orient and reassure child; provide calm, nonstimulating environment, use familiar music, verse, voice, touch Aromatherapy*: frankincense, ylang ylang

*Best if aromatherapy is administered by a practitioner trained in aromatherapy.
From Sourkes B, Frankel L, Brown M, et al: Food, toys, and love: pediatric palliative care, *Curr Probl Pediatr Adolesc Health Care* 35:345-392, 2005.

Many children with life-threatening illness experience pain that requires opioids for adequate relief at some point in their illness trajectory. Although it was previously recommended, prescribing codeine should generally be avoided because of its side-effect profile and lack of superiority over nonopioid analgesics. Furthermore, relatively common genetic polymorphisms in the CYP2D6 gene lead to wide variation in codeine metabolism. Specifically, 10-40% of individuals carry polymorphisms causing them to be "poor metabolizers" who cannot convert codeine to its active form, morphine, and therefore are at risk for inadequate pain control; others are "ultrametabolizers" who may even experience respiratory depression from rapid generation of morphine from codeine. It is therefore preferable to use a known amount of the active agent, morphine.

It is important to explore with families, as well as members of the care team, misconceptions that they may have regarding respiratory suppression, addiction, dependence, the symbolic meaning of starting an opioid such as methadone or morphine and/or a morphine drip, and the potential for opioids to hasten death. There is no association between administration or escalation of opioids and length of survival. Evidence supports longer survival in individuals with symptoms that are well controlled.

Children also often experience a multitude of **nonpain symptoms**. A combination of both pharmacologic (see Table 43-6) and nonpharmacologic approaches (see Table 43-7) is often optimal. **Fatigue** is one of the most common symptoms in children with advanced illness. Children may experience fatigue as a physical symptom (e.g., weakness or somnolence), a decline in cognition (e.g., diminished attention or concentration), and/or impaired emotional function (e.g., depressed mood or decreased motivation). Because of its multidimensional and incapacitating nature, fatigue can prevent children from participating in meaningful or pleasurable activities, thereby impairing quality of life. Fatigue is usually multifactorial in etiology. A careful history may reveal contributing physical factors (uncontrolled symptoms, medication side effects), psychological factors (anxiety, depression), spiritual distress, or sleep disturbance. Interventions to reduce fatigue include treatment of contributing factors, exercise, pharmacologic agents, and behavior modification strategies. Challenges to effectively addressing fatigue include the common belief that fatigue is inevitable, lack of communication between families and care teams about it, and limited awareness of potential interventions for fatigue.

Dyspnea (the subjective sensation of shortness of breath) is caused by a mismatch between afferent sensory input to the brain and the

outgoing motor signal from the brain. It may stem from respiratory causes (e.g., airway secretions, obstruction, infection) or other factors (e.g., cardiac), and may also be influenced by psychological factors (e.g., anxiety). Respiratory parameters such as respiratory rate and oxygen saturation correlate unreliably with the degree of dyspnea. Therefore, giving oxygen to a cyanotic or hypoxic child who is otherwise quiet and relaxed may relieve staff discomfort while having no impact on patient distress and may also add burden if the child cannot tolerate the mask or canula. Dyspnea can be relieved with the use of regularly scheduled *and* as-needed doses of opioids. Opioids work *directly* on the brainstem to reduce the sensation of respiratory distress, as opposed to relieving dyspnea via sedation. The dose of opioid needed to reduce dyspnea is as little as 25% of the amount that would be given for analgesia. Nonpharmacologic interventions, including guided imagery or hypnosis to reduce anxiety, or cool, flowing air, aimed toward the face, are also frequently helpful in alleviating dyspnea. While oxygen may relieve hypoxemia-related headaches, it is no more effective than blowing room air in reducing the distressing sensation of shortness of breath.

As death approaches, a buildup of secretions may result in noisy respiration sometimes referred to as a "death rattle." Patients at this stage are usually unconscious, and noisy respirations are often more distressing for others than for the child. It is often helpful to discuss this anticipated phenomenon with families in advance, and if it occurs, to point out the child's lack of distress from it. If treatment is needed, an anticholinergic medication, such as glycopyrrolate, may reduce secretions.

Neurologic symptoms include **seizures** that are often part of the antecedent illness but may increase in frequency and severity toward the end of life. A plan for managing seizures should be made in advance and anticonvulsants should be readily available in the event of seizure. Parents can be taught to use rectal diazepam at home. Increased **neuroirritability** accompanies some neurodegenerative disorders; it may be particularly disruptive because of the resultant break in normal sleep–wake patterns and the difficulty in finding respite facilities for children who have prolonged crying. Such neuroirritability may respond to gabapentin. Judicious use of sedatives, benzodiazepines, clonidine, nortriptyline, or methadone may also reduce irritability without inducing excessive sedation; such treatment can dramatically improve the quality of life for both child and caregivers. **Increased intracranial pressure** and **spinal cord compression** are most often encountered in children with brain tumors or metastatic and solid tumors. Depending on the clinical situation and the goals of care, radiation therapy, surgical interventions, and steroids are potential therapeutic options.

Feeding and hydration issues can raise ethical questions that evoke intense emotions in families and medical caregivers alike. Options that may be considered to artificially support nutrition and hydration in a child who can no longer feed by mouth include nasogastric and gastrostomy feedings or intravenous nutrition or hydration. These complex decisions require evaluating the risks and benefits of artificial feedings and taking into consideration the child's functional level and prognosis. At times, it may be appropriate to initiate a trial of tube feedings with the understanding that they may be discontinued at a later stage of the illness. A commonly held but unsubstantiated belief is that artificial nutrition and hydration are "comfort measures," without which a child may suffer from starvation or thirst. This may result in well-meaning but disruptive and invasive attempts to administer nutrition or fluids to a dying child. In dying adults, the sensation of thirst may be alleviated by careful efforts to keep the mouth moist and clean. There may also be deleterious side effects to artificial hydration in the form of increased secretions, need for frequent urination, edema and exacerbation of dyspnea. For these reasons, it is important to educate families about anticipated decreases in appetite/thirst and therefore little need for nutrition and hydration as the child approaches death. In addition, exploring the meaning that provision of nutrition and hydration may hold for families, as well as helping families anticipate the changes in their child's appearance and exploring alternative ways that they may love and nurture their child, may ease distress around this issue. **Nausea and vomiting** may be the result of a variety of causes, including medications/toxins, irritation to or obstruction of the gastrointestinal tract, motion, and emotions. Drugs such as metoclopramide, 5-hydroxytryptamine antagonists, steroids, and aprepitant may be used, and should be chosen depending on the underlying pathophysiology and neurotransmitters involved. Vomiting may accompany nausea but may also occur without nausea, such as in the instance of increased intracranial pressure. **Constipation** is commonly encountered in children with neurologic impairment or children receiving medications that impair gastrointestinal motility (most notably, opioids). Stool frequency and quantity should be evaluated in the context of the child's diet and usual bowel pattern. Children on regular opioids should routinely be placed on stool softeners (docusate) in addition to a laxative agent (e.g., senna). **Diarrhea** may be particularly difficult for the child and family and may be treated with loperamide (an opioid that does not cross the blood–brain barrier), and in some cases cholestyramine or octreotide may be indicated. Paradoxical diarrhea, a result of overflow resulting from constipation, should also be included in the differential diagnosis.

Hematologic issues include consideration of anemia and thrombocytopenia or bleeding. If the child has symptomatic anemia (weakness, dizziness, shortness of breath, tachycardia), red blood cell transfusions may be considered. Platelet transfusions may be an option if the child has symptoms of bleeding. Life-ending hemorrhage is disturbing for all concerned, and a plan involving the use of fast-acting sedatives should be prepared in advance if such an event is a possibility.

Skin care issues include primary prevention of problems by ongoing and timely assessment including observation of indwelling lines and tubes, and frequent turning and repositioning and alleviating pressure wherever possible (e.g., elevating heels with pillows). Pruritus may be secondary to systemic disorders or drug therapy. Treatment includes avoiding excessive use of drying soaps, using moisturizers, trimming fingernails, and wearing loose-fitting clothing, in addition to administering topical or systemic steroids. Oral antihistamines and other specific therapies may also be indicated (e.g., cholestyramine in biliary disease). Although opioids can cause histamine release from mast cells, this does not account for most of the pruritus caused by opioids. A trial of diphenhydramine may provide relief; alternatively, rotating opioids or instituting a low dose of opioid antagonist may be needed for refractory pruritus.

Children with life-threatening illness may experience psychological symptoms such as **anxiety** and **depression.** Such symptoms are frequently multifactorial, and sometimes interrelated with uncontrolled symptoms such as pain and fatigue. Diagnosing depression in the context of serious illness may pose challenges since neurovegetative symptoms may not be reliable indicators. Instead, expressions of hopelessness, helplessness, worthlessness, and guilt may be more useful. Pharmacologic agents such as antidepressants may be helpful, although their effect is often preceded by a significant lag phase. Because of its immediate and positive effect on mood, methylphenidate may be an effective antidepressant for children at end of life, when there may not be time for a traditional antidepressant to take effect. Interventions and opportunities for children to explore worries, hopes, and concerns in an open, supportive, and nonjudgmental setting are equally if not more important approaches to psychological distress. Skilled members from a variety of disciplines, including psychology, social work, chaplaincy, child life, and expressive therapy, among others, may help children and their families in this regard. Such opportunities may in fact create positive moments in which meaning, connection, and new definitions of hope are found.

Discussions with adolescent patients or with the parents of any ill child, about possible therapies or interventions should include **integrative therapies** such as massage therapy, Reiki, acupuncture, clinical aromatherapy, prayer, and nutritional supplements. Many families use integrative therapy, but do not bring it up with their physician unless explicitly asked (see Chapter 64). Although largely unproven, some therapies are inexpensive and provide relief to individual

patients. Other therapies may be expensive, painful, intrusive, and even toxic. By initiating conversation and inviting discussion in a nonjudgmental way, the clinician can offer advice on the safety of different therapies and may help avoid expensive, dangerous, or burdensome interventions.

Intensive Symptom Management

At end of life, when intensive efforts to relieve the symptom have been exhausted, or when efforts to address suffering are incapable of providing relief with acceptable toxicity/morbidity or in an acceptable time frame, **palliative sedation** may be considered. Palliative sedation may relieve suffering from refractory symptoms by reducing a child's level of consciousness. It is most often used for intractable pain, dyspnea, or agitation, but is not limited to these distressing indications. Palliative sedation requires opportunities for parents, staff, and primary clinicians to discuss the indication and goals for sedation, as well as questions or concerns about this therapy, both before and after initiation of sedation.

The *principle of double effect* is often invoked to justify escalation of symptom-relieving medications or palliative sedation for uncontrolled symptoms at the end of life. Use of this principle emphasizes the risk of hastening death posed by escalating opioids or sedation, which is theoretical and unproven. There is mounting evidence that patients with well-controlled symptoms live longer.

The Terminal Phase

As death seems imminent, the major task of the physician and team are to help the child have as many good days as possible and not suffer. If not already in place, a referral to **hospice** may provide the most comprehensive care for the child and family. Gently preparing the family for what to expect and offering choices, when possible, will allow them a sense of control in the midst of tragic circumstances. Before death, it can be very helpful to discuss:

- Support of siblings or other family members
- Resuscitation status
- Limiting technology when no longer beneficial to the child
- Cultural, spiritual, or religious needs
- Location of death
  - Who will pronounce if death occurs at home
- Funeral arrangements
  - Offering siblings choice and appropriate support to attend
- Autopsy and/or tissue or organ donation
  - Legacy building, benefits others, informs science and family

Offered the opportunity, families will often tolerate thinking and speaking about their hopes and fears regarding their child's end of life, and some even express relief when the door to such conversation in opened by the care team. It may help to let the family know these conversations are not about *whether* the child will die, but about *how* the child may die.

Families gain tremendous support from having a physician and team who will continue to stay involved in the child's care. If the child is at home or hospitalized, regular phone calls or visits, assisting with symptom management, and offering emotional support is invaluable for families.

In an intensive care setting, where technology can be overwhelming and put distance between the child and parent, the physician can offer discontinuation of that which is not benefiting the child or adding to quality of life. Parents may be afraid to ask about holding or sleeping next to their child. They may need reassurance and assistance in holding, touching, and speaking with their child, despite tubes and technology, even if the child appears unresponsive.

It is believed that hearing and the ability to sense touch is often present until death; all family members should be encouraged to continue interacting with their loved one through the dying process. Parents may be afraid to leave the bedside so that their child will not die alone. Offering parents other supports such as chaplaincy/clergy, social work and extended family members may be helpful. In most instances the moment of death cannot be predicted. Some propose that children wait to die until parents are "ready," an important event has passed, or until they are given permission. Caregivers need not dispute this, nor the hope for a miracle often held by families until the child takes the very last breath.

For the family, the moment of death is an event that is recalled in detail for years to come, and so enhancing opportunity for dignity and limited suffering is essential. Research suggests that improved symptom control and easing of difficult moments at the time of death may lessen the long-term distress of bereaved parents. Clinical experience has shown that families often find solace in clinician "presence," whether at home or in the hospital. After death, families should be given the option of remaining with their child for as long as they would like. During this time, physicians and other professionals may ask permission to "say goodbye." The family may be invited to bathe and dress the body as a final act of caring for the child.

The physician's decision to attend the funeral is a personal one. Participation may serve the dual purpose of showing respect as well as helping the clinician cope with a personal sense of loss. If unable to attend services, families report highly valuing the importance of receiving a card or note from the physician. To know that their child made a difference and will not be forgotten is often very important to families in their bereavement.

The Pediatrician

While optimal palliative care for children entails caregivers from a variety of disciplines, pediatricians are well-positioned to support children and their families, particularly if they have a long-standing relationship with multiple family members. A pediatrician who has cared for a family over time may already know and care for other family members, understand preexisting stressors for the family, and may be familiar with coping strategies used by family members. Pediatricians are familiar with the process of eliciting concerns and providing anticipatory guidance for parents, as well as developmentally appropriate explanations for children.

Nutrition

PART VI

Chapter 44

Nutritional Requirements

Elizabeth P. Parks, Asim Maqbool, Ala Shaikhkhalil, Veronique Groleau, Kelly A. Dougherty, and Virginia A. Stallings

Nutritional intakes for infants, children, and adolescents should provide for maintenance of current weight and support normal growth and development. The infancy growth period is rapid, critical for neurocognitive development, and has the highest energy and nutrient requirements relative to body size compared with other periods of growth. It is followed by the childhood period of growth, during which 60% of total growth occurs, and is finally followed by the puberty phase. Nutrition and growth during the first 3 years of life predict adult stature and some health outcomes. The major risk period for growth stunting (impaired linear growth) is between 4 and 24 months of age. It is critical to identify nutrient deficiencies promptly and to address them aggressively early in life, because they can impart lasting adverse effects on growth and development. Dietary intake not only meets energy requirements but also provides macronutrients and micronutrients essential for sustaining the functioning of multiple vital processes. Nutrient deficiencies can limit growth, impair immune function, and increase morbidity and mortality. The significant global burden of malnutrition and undernutrition is the leading worldwide cause of acquired immunodeficiency and the major underlying factor for morbidity and mortality globally for children <5 yr of age.

The nutrition transition in many developing countries as populations change from traditional diets to the Western diet has resulted in increased life expectancy and adult stature in these populations. Unfortunately, this nutrition transition is also frequently accompanied by decreased physical activity, and in parallel to decreases in the incidence and prevalence of communicable (infectious) diseases, there are increases in the incidence and prevalence of noncommunicable diseases such as noninsulin-dependent diabetes, cardiovascular disease, obesity, inflammatory bowel disease, and certain cancers.

Consequently, it is important to view the impact of nutrition on health from various perspectives: to prevent deficiency, to promote adequacy, and to prevent or reduce the risk for acquiring diseases associated with excess intakes, such as obesity, diabetes, and cardiovascular disease. Advances in our understanding of the roles of vitamin D, polyunsaturated fatty acids (PUFAs), and total fiber have changed our focus from recommendations for deficiency to nutritional intakes associated with optimal health. In addition, the 2006 World Health Organization (WHO) growth charts, *which are recommended for all children until 2 years of age*, are not only descriptive, but are also proscriptive on how children with adequate nutrition and health care should grow. Identification and provision of appropriate and adequate nutrition in infancy and childhood are critical to not only support normal growth and development, but also to provide the foundation for lifelong health and well-being.

DIETARY REFERENCE INTAKES

The dietary reference intake (DRI) established by the Food and Nutrition Board of the Institute of Medicine provides guidance as to nutrient needs for individuals and groups across different life stages and by gender (Tables 44-1 to 44-4).

Key DRI concepts include the estimated average requirement (EAR), the recommended dietary allowance (RDA), and the tolerable upper limit of intake (UL) (Fig. 44-1). The EAR is the average daily nutrient intake level estimated to meet the requirements for 50% of the population, assuming normal distribution; the RDA is an estimate of the daily average nutrient intake to meet the nutritional needs of >97% of the individuals in a population, and it can be used as a guideline for individuals to avoid deficiency in the population. When an EAR cannot be derived, an RDA cannot be calculated; therefore, an adequate intake (AI) is developed as a guideline for individuals based on the best available data and scientific consensus. The UL denotes the highest average daily intake at which no adverse health effects are associated for almost all individuals in a particular group. The relationships among EAR, RDA, and UL are characterized in Figure 44-2.

ENERGY

Energy includes both intake and expenditure. Deficits and excesses of energy intake yield undesirable health consequences. Inadequate energy intake can lead to growth faltering, catabolism of body tissues and inability to provide energy substrate, whereas excess energy intakes can increase the risk for obesity. Adequacy of energy intake in adults is associated with maintenance of a healthy weight. The 3 components of energy expenditure in adults are the basal metabolic rate, thermal effect of food (energy required for digestion and absorption), and energy for physical activity. Additional energy intake is required to support growth and development for children.

The **estimated energy requirement (EER)** is the average dietary energy intake predicted to maintain energy balance in a healthy individual and accounts for age, gender, weight, stature, and physical activity level (see Table 44-1). The Dietary Guidelines for Americans 2010 recommend 60 min of moderately intense daily activity for children >2 yr of age to maintain a healthy weight and to prevent or delay progression of chronic noncommunicable diseases such as obesity and cardiovascular disease. The EER was determined based on empirical research in healthy persons at different physical activity levels, including levels different from the recommended levels. *They do not necessarily apply to children with acute or chronic diseases*. EER is estimated by equations that account for total energy expenditure, as well as energy deposition for healthy growth. The EER for infants, relative to body weight, are approximately twice those for adults because of the increased metabolic rate and requirements for weight maintenance and tissue accretion affecting growth.

The nutrients that provide energy intake in the child's diet are fats (~9 kcal/g), carbohydrates (~4 kcal/g), and proteins (~4 kcal/g). They are referred to as **macronutrients**. Alcohol intake also contributes to energy intake (~7 kcal/g). The EER does not specify the relative energy contributions of macronutrients. Once the minimal intakes of each of the respective macronutrients are attained to meet physiologic requirements and to achieve adequacy (sufficient protein intake to meet specific amino acid requirements, fat for essential fatty acids, and neurologic development), the remainder of the intake is used to meet energy requirements with some degrees of freedom and interchangeability among fats, carbohydrates, and proteins. This forms the basis for the acceptable macronutrient distribution ranges (AMDRs) (see Table 44-2), expressed as a function of total energy intake.

Table 44-1	Equations to Estimate Energy Requirement
INFANTS AND YOUNG CHILDREN: EER (KCAL/DAY) = TEE + ED	
0-3 mo	EER = (89 × weight [kg] − 100) + 175
4-6 mo	EER = (89 × weight [kg] − 100) + 56
7-12 mo	EER = (89 × weight [kg] − 100) + 22
13-36 mo	EER = (89 × weight [kg] − 100) + 20
CHILDREN AND ADOLESCENTS 3-18 YR: EER (KCAL/DAY) = TEE + ED	
Boys	
3-8 yr	EER = 88.5 − (61.9 × age [yr] + PA × [(26.7 × weight [kg] + (903 × height [m])] + 20
9-18 yr	EER = 88.5 − (61.9 × age [yr] + PA × [(26.7 × weight [kg] + (903 × height [m])] + 25
Girls	
3-8 yr	EER = 135.3 − (30.8 × age [yr] + PA [(10 × weight [kg] + (934 × height [m])] + 20
9-18 yr	EER = 135.3 − (30.8 × age [yr] + PA [(10 × weight [kg] + (934 × height [m])] + 25

ED, energy deposition; EER, estimated energy requirement; TEE, total energy expenditure.

PA indicates the physical activity coefficient:

For boys:
- PA = 1.00 (sedentary, estimated physical activity level 1.0-1.4)
- PA = 1.13 (low active, estimated physical activity level 1.4-1.6)
- PA = 1.26 (active, estimated physical activity level 1.6-1.9)
- PA = 1.42 (very active, estimated physical activity level 1.9-2.5)

For girls:
- PA = 1.00 (sedentary, estimated physical activity level 1.0-1.4)
- PA = 1.16 (low active, estimated physical activity level 1.4-1.6)
- PA = 1.31 (active, estimated physical activity level 1.6-1.9)
- PA = 1.56 (very active, estimated physical activity level 1.9-2.5)

Adapted from Kleinman RE, editor: Pediatric nutrition handbook, *ed 6, Elk Grove Village, IL, 2009, American Academy of Pediatrics.*

FAT

Fat is the most calorically dense macronutrient, providing approximately 9 kcal/g. For infants, human milk/formula are the main dietary sources of fat, whereas older children get fat from animal products, vegetable oils, and margarine. The AMDR for fats is 30-40% of total energy intake for children 1-3 yr and 25-35% for children 4-18 yr of age. In addition to being energy-dense, fats provide essential fatty acids and play structural and functional roles; cholesterol moieties are precursors for cell membranes, hormones, and bile acids. Fat intake facilitates absorption of fat-soluble vitamins A, D, E, and K. Both roles are particularly relevant in the context of neurological and ocular development.

Table 44-2 Acceptable Macronutrient Distribution Ranges

	AMDR (% OF ENERGY)	
	Children 1-3 yr	**Children 4-18 yr**
Fat	30-40	25-35
ω6 PUFAs (linoleic acid)	5-10	5-10
ω3 PUFAs (α-linolenic acid)	0.6-1.2	0.6-1.2
Carbohydrate	45-65	45-65
Protein	5-20	10-30

AMDR, acceptable macronutrient distribution range; PUFA, polyunsaturated fatty acid.

Table 44-3 Dietary Reference Intakes: Macronutrients

FUNCTION	LIFE STAGE GROUP	RDA OR AI* (g/day)	SELECTED FOOD SOURCES	ADVERSE EFFECTS OF EXCESSIVE CONSUMPTION
TOTAL DIGESTIBLE CARBOHYDRATE				
RDA based on its role as the primary energy source for the brain AMDR based on its role as a source of kcal to maintain body weight	*Infants* 0-6 mo 7-12 mo *Children* >1 yr *Pregnancy* ≤18 yr 19-30 yr	 60* 95* **130** **175** **175**	Major types: starches and sugars Grains and vegetables (corn, pasta, rice, potatoes, breads) are sources of starch Natural sugars are found in fruits and juices Sources of added sugars: soft drinks, candy, fruit drinks, desserts	No defined intake level for potential adverse effects of total digestible carbohydrate is identified, but the upper end of the AMDR was based on decreasing risk of chronic disease and providing adequate intake of other nutrients It is suggested that the maximal intake of added sugars be limited to providing no more than 25% of energy
TOTAL FIBER				
Improves laxation, reduces risk of coronary heart disease, assists in maintaining normal blood glucose levels	*Infants* 0-6 mo 7-12 mo *Children* 1-3 yr 4-8 yr *Males* 9-13 yr 14-18 yr 19-21 *Females* 9-13 yr 14-18 yr 19-21 yr *Pregnancy* ≤18 yr 19-21 yr	 ND ND 190* 25* 31* 38* 38* 26* 26* 25* 28* 28*	Includes dietary fiber naturally present in grains (e.g., oats, wheat, unmilled rice) and functional fiber synthesized or isolated from plants or animals and shown to be of benefit to health	Dietary fiber can have variable compositions; therefore, it is difficult to link a specific source of fiber with a particular adverse effect, especially when phytate is also present in the natural fiber source As part of an overall healthy diet, a high intake of dietary fiber will not produce deleterious effects in healthy persons Occasional adverse GI symptoms are observed when consuming some isolated or synthetic fibers, but serious chronic adverse effects have not been observed Owing to the bulky nature of fibers, excess consumption is likely to be self-limiting; therefore, an UL was not set for individual functional fibers

Continued

Table 44-3 Dietary Reference Intakes: Macronutrients—cont'd

FUNCTION	LIFE STAGE GROUP	RDA OR AI* (g/day)	SELECTED FOOD SOURCES	ADVERSE EFFECTS OF EXCESSIVE CONSUMPTION
TOTAL FAT				
Energy source When found in foods, is a source of ω3 and ω6 PUFAs Facilitates absorption of fat-soluble vitamins	*Infants* 0-6 mo 7-12 mo 1-18 yr	 31* 30* Insufficient evidence to determine AI or EAR; see AMDR Table 41-4	Infants: Human milk or infant formula Older children: butter, margarine, vegetable oils, whole milk, visible fat on meat and poultry products, invisible fat in fish, shellfish, some plant products such as seeds and nuts, bakery products	UL not set because there is no defined intake of fat at which adverse effects occur. High fat intake will lead to obesity. The upper end of AMDR is also based on decreasing risk of chronic disease and providing adequate intake of other nutrients Low fat intake (with high carbohydrate) has been shown to increase plasma triacylglycerol concentrations and decrease HDL cholesterol
ω6 POLYUNSATURATED FATTY ACIDS				
Essential component of structural membrane lipids, involved with cell signaling, precursor of eicosanoids Required for normal skin function	*Infants* 0-6 mo 7-12 mo *Children* 1-3 yr 4-8 yr *Males* 9-13 yr 14-18 yr 19-21 yr *Females* 9-13 yr 14-18 yr 19-21 yr *Pregnancy* ≤18 yr 19-21 yr *Lactation* ≤18 yr 19-21 yr	 4.4* 4.6* 7* 10* 12* 16* 17* 10* 11* 12* 13* 13* 13* 13*	Nuts, seeds; vegetable oils such as soybean, safflower, corn oil	No defined intake of ω6 level at which adverse effects occur Upper end of the AMDR is based on the lack of evidence that demonstrates long-term safety and human in vitro studies that show increased free-radical formation and lipid peroxidation with higher amounts of ω6 fatty acids Lipid peroxidation is thought to be a component of atherosclerotic plaques
ω3 POLYUNSATURATED FATTY ACIDS				
Involved with neurologic development and growth Precursor of eicosanoids	*Infants* 0-6 mo 7-12 mo *Children* 1-3 yr 4-8 yr *Males* 9-13 yr 14-18 yr 19-21 yr *Females* 9-13 yr 14-18 yr 19-21 yr *Pregnancy* ≤18 yr 19-21 yr *Lactation* ≤18 yr 19-21 yr	 0.5* 0.5* 0.7* 0.9* 1.2* 1.6* 1.6* 1.0* 1.1* 1.1* 1.1* 1.4* 1.3* 1.3*	Vegetable oils, e.g., soybean, canola, flax seed oil; fish oils, fatty fish; smaller amounts in meats and eggs	No defined intake level for potential adverse effects of ω3 PUFAs is identified Upper end of AMDR is based on maintaining the appropriate balance with ω6 fatty acids and on the lack of evidence that demonstrates long-term safety, along with human in vitro studies that show increased free-radical formation and lipid peroxidation with higher amounts of PUFAs Because the longer-chain *n*-3 fatty acids, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), are biologically more potent than their precursor, linolenic acid, much of the work on the adverse effects of this group of fatty acids has been on DHA and EPA Lipid peroxidation is thought to be a component in the development of atherosclerotic plaques
SATURATED AND *TRANS* FATTY ACIDS				
The body can synthesize its needs for saturated fatty acids from other sources		No dietary requirement	Saturated fatty acids are present in animal fats (meat fats and butter fat), and coconut and palm kernel oils *Trans* fat: stick margarines, foods containing hydrogenated or partially hydrogenated vegetable shortenings	There is an incremental increase in plasma total and LDL cholesterol concentrations with increased intake of saturated or *trans* fatty acids; therefore, the intakes of each should be minimized while consuming a nutritionally adequate diet

Table 44-3 Dietary Reference Intakes: Macronutrients—cont'd

FUNCTION	LIFE STAGE GROUP	RDA OR AI* (g/day)	SELECTED FOOD SOURCES	ADVERSE EFFECTS OF EXCESSIVE CONSUMPTION
CHOLESTEROL				
		No dietary requirement	Sources: liver, eggs, foods that contain eggs, e.g., cheesecake, custard pie	
PROTEIN AND AMINO ACIDS†				
Major structural component of all cells in the body Functions as enzymes, in membranes, as transport carriers, and as some hormones During digestion and absorption, dietary proteins are broken down to amino acids, which become the building blocks of these structural and functional compounds Nine indispensable amino acids must be provided in the diet; the body can make the other amino acids needed to synthesize specific structures from other amino acids	*Infants*		Proteins from animal sources, e.g., meat, poultry, fish, eggs, milk, cheese, yogurt, provide all 9 indispensable amino acids in adequate amounts and are considered "complete proteins" Proteins from plants, legumes, grains, nuts, seeds, and vegetables tend to be deficient in ≥1 of the indispensable amino acids and are called "incomplete proteins" Vegan diets adequate in total protein content can be "complete" by combining sources of incomplete proteins, which lack different indispensable amino acids	No defined intake level for potential adverse effects of protein is identified Upper end of AMDR was based on complementing the AMDR for carbohydrate and fat for the various age groups Lower end of AMDR is set at approximately the RDA
	0-6 mo	9.1*		
	7-12 mo	**11.0**		
	Children			
	1-3 yr	**13**		
	4-8 yr	**19**		
	Males			
	9-13 yr	**34**		
	14-18 yr	**52**		
	≥19 yr	**56**		
	Females			
	9-13 yr	**34**		
	≥14 yr	**46**		
	≤18 yr			
	19-21 yr	**71**		

Note: Starred numbers are AI; bold numbers are RDA. RDAs and AIs may both be used as goals for individual intake. RDAs are set to meet the needs of 97-98% of members in a group. For healthy breast-fed infants, the AI is the mean intake. The AI for other life-stage and gender groups is believed to cover the needs of all members of the group, but lack of data prevents specifying with confidence the percentage covered by this intake. AMDR is the range of intake for a particular energy source that is associated with reduced risk of chronic disease while providing intakes of essential nutrients. With consumption in excess of the AMDR, there is a potential for increasing the risk of chronic diseases and/or insufficient intakes of essential nutrients. ND amounts are not determinable because of a lack of data regarding adverse effects in this age group and concern with regard to a lack of ability to handle excess amounts. Source of intake should be from food only to prevent high levels of intake.

*Adequate intake.

†Based on 1.5 g/kg/day for infants, 1.1 g/kg/day for 1-3 yr, 0.95 g/kg/day for 4-13 yr, 0.85 g/kg/day for 14-18 yr, 0.8 g/kg/day for adults, and 1.1 g/kg/day for pregnant (using prepregnancy weight) and lactating women.

AI, adequate intake; AMDR, acceptable macronutrient distribution range; GI, gastrointestinal; LDL, low-density lipoprotein (cholesterol); ND, not determinable; PUFA, polyunsaturated fatty acid; RDA, recommended dietary allowance; UL, upper limit.

Adapted from Food and Nutrition Board, Institute of Medicine: Dietary reference intakes for energy, carbohydrate, fiber, fat, fatty acids, cholesterol, protein, and amino acids *http://www.iom.edu/Activities/Nutrition/SummaryDRIs/DRI-Tables.aspx*.

Table 44-4 Indispensable, Dispensable, and Conditionally Indispensable Amino Acids in the Human Diet

INDISPENSABLE	DISPENSABLE	CONDITIONALLY INDISPENSABLE*	PRECURSORS OF CONDITIONALLY INDISPENSABLE
Histidine†	Alanine	Arginine	Glutamine/glutamate, aspartate
Isoleucine	Aspartic acid	Cysteine	Methionine, serine
Leucine	Asparagine	Glutamine	Glutamic acid/ammonia
Lysine	Glutamic acid	Glycine	Serine, choline
Methionine	Serine	Proline	Glutamate
Phenylalanine		Tyrosine	Phenylalanine
Threonine			
Tryptophan			
Valine			

*Conditionally indispensable is defined as requiring a dietary source when endogenous synthesis cannot meet metabolic need.

†Although histidine is considered indispensable, unlike the other 8 indispensable amino acids, it does not fulfill the criteria of reducing protein deposition and inducing negative nitrogen balance promptly upon removal from the diet.

Adapted from Otten JJ, Hellwig JP, Meyers LD, editors; Institute of Medicine: Dietary reference intakes: the essential guide to nutrient requirements, *Washington, DC, 2006, National Academies Press.*

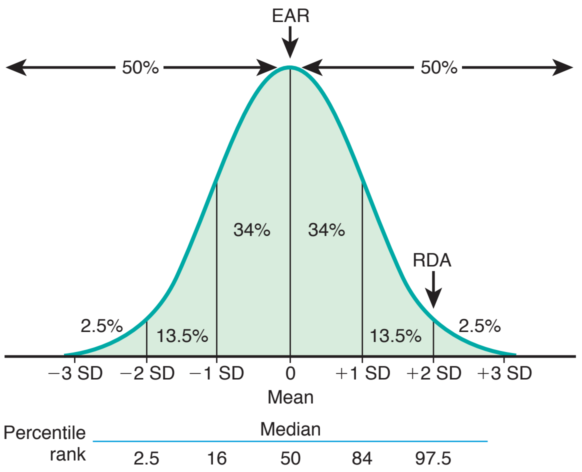

Figure 44-1 **Dietary reference intakes.** Normal requirement distribution of hypothetical nutrient showing percentile rank and placement of the estimated average requirement (EAR) and the recommended dietary allowance (RDA) on the distribution. SD, standard deviation.

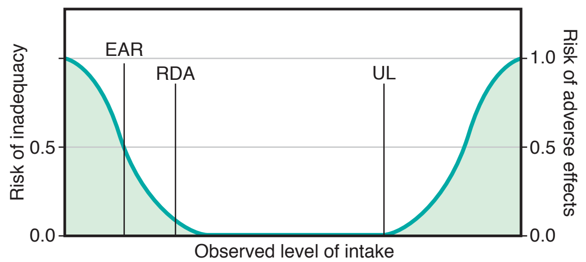

Figure 44-2 **Dietary reference intakes: the relationship among the estimated average requirement (EAR), the recommended dietary allowance (RDA), and the tolerable upper limit of intake (UL).** This figure shows that the EAR is the intake at which the risk of inadequacy is estimated to be 0.5 (50%). The RDA is the intake at which the risk of inadequacy would be very small—only 0.02 to 0.03 (2-3%). At intakes between the RDA and the UL, the risk of inadequacy and of excess are estimated to be close to 0.0. At intakes above the UL, the potential risk of adverse effects can increase.

Triglycerides are the most common form of dietary fat and are composed of 1 glycerol molecule and 3 fatty acids. Triglycerides are found in animal and vegetable fats. Simple sugars (refined grains and high sugar drinks) are converted to triglycerides in the liver. Elevated serum triglycerides are a risk factor for cardiovascular disease and part of the metabolic syndrome. Decreasing simple sugars and increasing complex carbohydrate intake reduce serum triglyceride levels.

Dietary saturated fatty acids (found primarily in animal fat and dairy products), *trans* fats (found in hydrogenated margarines and oils), and cholesterol increase the low-density lipoprotein (LDL) fraction of serum cholesterol, a risk factor for the development of atherosclerosis. Autopsy studies demonstrate that atherosclerosis begins early in childhood, even in infancy. Therefore, dietary advice to optimize cardiovascular health should be dispensed for children starting at age 2 yr when sufficient fat intake to sustain growth and brain development is less of a concern.

Because saturated and monounsaturated fats can be synthesized endogenously to support adequate structural and physiologic requirements, there is no AI or RDA set for these dietary components. *Trans* fats have no known beneficial effects in humans; therefore, no corresponding AI or RDA has been set. Similarly, an UL has not been set for cholesterol, saturated, or *trans* fats because there is a positive linear association between intake of these fats and increased risk for cardiovascular disease, without a threshold level at which risk is increased. Diets low in saturated fats and cholesterol and without *trans* fats are therefore preferred. For optimal cardiovascular health in the general population, rather than limiting the total amount of fat intake, in most cases, advice should focus on changing the type of fat that is consumed. With respect to preventing obesity, all types of fatty acids have about the same energy content and can contribute to increasing the risk for obesity. The current dietary guidelines for children and adolescents recommend that total fat should account for <30% of total daily energy and saturated fat less than 10%, dietary cholesterol <300 mg/day, with no *trans* fat.

Humans are incapable of synthesizing the precursor omega (ω) 3 (α-linolenic acid; ALA) and ω6 (linoleic acid; LA) PUFAs, and are dependent on diet for these essential fatty acids. **Essential fatty acid (EFA) deficiency** is associated with desquamating skin rashes, alopecia, thrombocytopenia, impaired immunity, and growth deficits, but is rare in the general population. Essential fatty acids are enzymatically elongated and desaturated into longer-chain fatty acids; ALA can be converted to eicosapentaenoic (EPA) and docosahexaenoic (DHA) ω3 PUFAs. LA is converted to arachidonic acid (ARA). Long-chain PUFAs such as DHA and ARA play a variety of structural and functional roles; they influence membrane fluidity and function as well as gene expression, and modulate the inflammatory response. ARA and DHA are present in breast milk, often supplemented in infant formulas, and are required for normal growth and development. DHA is present in the retina and is involved in the visual evoked response in infants.

The conversion of ALA to EPA and DHA and of LA to ARA is influenced by many factors, including type and amounts of dietary fats and by enzymatic substrate affinity among competing ω3, ω6, ω9, saturated, and *trans* fatty acids. The efficiency in conversion of ALA to a longer-chain PUFA is minimal and variable. Approximately 0.5% of dietary ALA is converted to DHA and 5% of ALA intake converted to EPA; therefore, dietary intake of longer-chain PUFAs is an important determinant of serum and tissue long-chain PUFA status. The biologic activity and health benefits of ALA are thought to be derived via the longer-chain PUFA products EPA and DHA. Consistent with these findings of limited conversion of ALA to EPA and DHA, and that EPA and DHA appear to confer the biologic role and health benefits, the DRI stipulates that up to 10% of the AI for ω3 PUFA (ALA being the major dietary constituent) can be replaced by DHA and EPA to support normal neural development and growth.

The ratio of dietary intake of each type of PUFA influences their relative amounts in different tissue compartments. A dietary ω6:ω3 PUFA ratio of 4-5 : 1 may be beneficial in reducing risk of disease and may be associated with improved health outcomes, as compared to the current 15-30 : 1 ratio observed in the United States.

PROTEINS

Proteins and amino acids have structural and functional roles in every cell in the body. Proteins also provide approximately 4 kcal/g; however, dietary protein intake is required to replenish the turnover of proteins and to meet amino acid needs for growth. Dietary protein intake also provides energy substrate when in excess or during periods of catabolism. Inadequate energy intake and/or inadequate protein intake increases catabolism of body protein reservoirs (i.e., lean body mass) so as to provide substrate for energy and free amino acids required to support normal physiologic function. Nitrogen losses, derived from proteins, occur through urine, stool, and other bodily excretions. Increased protein intake may be required for rare hypermetabolic states, such as extensive burns. Protein energy malnutrition, although relatively rare in the noninstitutionalized U.S. population, is more common in the developing world. Protein energy malnutrition impairs brain, immune system and intestinal mucosal functions.

DRI for protein is provided in Table 44-3. An UL for protein has not been set. Intake of proteins or specific amino acids needs to be limited in some health conditions, such as renal disease and metabolic diseases, such as phenylketonuria and maple syrup urine disease, in which specific amino acids can be toxic.

The amino acid content of dietary protein is also important. Certain amino acids are **indispensable** and humans depend on dietary sources to meet adequacy and prevent deficiency. Certain amino acids are

termed **conditional essential/indispensable**, meaning they become essential in patients affected by some diseases or during a certain life stage, such as with cysteine, tyrosine and arginine in newborns because of enzymes immaturity (see Table 44-4). Human milk contains both the indispensable and conditionally indispensable amino acids and therefore meets the protein requirements for infants. Breast milk is considered the optimal source of proteins for infants and is the reference amino acid composition by which biologic quality is determined for infants. If a single amino acid in a food protein source is low or absent but is required to support normal metabolism, that specific amino acid becomes the limiting nutrient. For soy-based infant formula, supplementation with the limiting amino acid (methionine) is necessary.

To ensure appropriate growth and to promote satiety, children should consume the recommended amount of protein. Specific recommendations for appropriate dietary protein sources to meet indispensable amino acid requirements are available for groups adopting specific diets, such as vegetarians and vegans. Inclusion of legumes and corn, as well as the use of a variety of food sources to provide all of the required amino acids is a strategy advocated for vegetarians and vegans.

CARBOHYDRATES

Carbohydrates are abundant in many foods, including cereals, grains, fruits, and vegetables, and provide approximately 4 kcal/g. Dietary carbohydrates include monosaccharides, which contain 1 sugar molecule (glucose, fructose), disaccharides that contain 2 sugar molecules (sucrose, lactose), oligosaccharides, polysaccharides (which contain multiple sugar molecules in a chain or complex configuration) (starch), and sugar alcohols. Carbohydrates (glucose) serve as an essential energy source for erythrocytes and the central nervous system and a major energy source for all cells. The requirements for carbohydrates are based on the average minimum amount of glucose utilized by the brain. Chronic low carbohydrate intake results in ketosis. Although an UL for carbohydrates has not been set, a maximal intake of <25% or <10% of total energy intake from added sugars has been proposed in various dietary guidelines. Higher intakes of added sugar can displace other macro- and micronutrients and increase risk for nutrient deficiency and excessive energy intake. There is no distinct advantage or benefit obtained from discretionary calorie intake such as that provided by the consumption of added sugars.

The recommended AMDR for carbohydrates (see Table 44-2) were based upon data suggesting a risk for coronary heart disease with diets high in carbohydrates and low in fat. These diets, compared to higher fat intakes, result in high triglycerides, low high-density lipoprotein (HDL) cholesterol, and small LDL cholesterol particles and are associated with a high risk of coronary heart disease, especially in sedentary overweight individuals. Diets within the AMDR for carbohydrates and fats minimize the risks of diabetes, obesity and coronary heart disease. Diets with less than the minimum AMDR for carbohydrate most likely do not meet the AI for fiber (see Table 44-3).

The majority of carbohydrates are present as starches or sugars in food. Simple sugars (mono- and disaccharides) are often added to foods and beverages during food preparation, processing, and packaging to enhance palatability and as preservatives. Nondiet soft drinks, juice drinks, iced tea, and sport drinks are among the major contributors to added sugars in the diet of U.S. children and adolescents. Added sugars increase the risk for obesity, diabetes, and dental caries. Fructose is one such added sugar in the form of high-fructose corn syrup, which is nearly ubiquitous in the U.S. diet. Fructose increases HDL and triglyceride production in the liver and serum uric acid levels which increase systolic blood pressure and is associated with fatty liver disease and metabolic syndrome. Excessive fructose intake, such as in the form of fruit juices, is associated with diarrhea, abdominal pain, and failure to thrive in children.

The **glycemic index** is a measure of the height of blood sugar levels 2 hours following ingestion against the reference standard (a slice of white bread). The glycemic index has predictable effects on blood glucose, hemoglobin A_{1C}, insulin, triglycerides, and HDL cholesterol levels. Lower glycemic index foods are recommended and may reduce the risk of insulin resistance and cardiovascular disease.

FIBER

Fiber consists of nondigestible carbohydrates mostly derived from plant sources, such as whole grain, fruits, and vegetables, that escape digestion and reach the colon nearly 100% intact. These compounds were previously classified as being water soluble versus insoluble, which may be a relatively less meaningful distinction, although still commonly used. The DRI classification lists **dietary fiber** (nondigestible carbohydrates and lignin that are intrinsic and intact in plants), **functional fiber** (with known physiologic benefits in humans), and **total fiber** (dietary plus functional).

Although fiber intake does not contribute significantly to energy intake, it does play several important roles. The metabolic fate of fiber is influenced primarily by the colonic bacteria, which depending on the structure of the fiber, can render it susceptible to fermentation (e.g., pectin and oat bran). Common by-products of colonic fermentation include carbon dioxide, methane (in addition to other gases), **oligofructases** (also known as prebiotics-substrates that nourish beneficial commensurate gastrointestinal microbiota), and **short-chain fatty acids (SCFAs)**. The common SCFAs produced by fermentation include acetate, butyrate, and propionate. There is dynamic interplay between the colonic bacterial milieu and the diet. SCFAs influence colonic physiology by stimulating colonic blood flow and fluid and electrolyte uptake. Butyrate is the preferred fuel for the colonocyte, and it might have a role in maintaining the normal phenotype in these cells.

Dietary fiber might play an important role by diluting toxins, carcinogens, and tumor promoters; by decreasing transit time, thereby decreasing colonic mucosal exposure; and by promoting their expulsion in the fecal stream. Dietary fiber resistant to colonic degradation might also play a role in maintaining and promoting stool bulk and in the regulation of intraluminal pressure and colonic wall resistance, disordered colonic motility, or both. Lack of dietary fiber is associated with constipation and diverticulosis.

All fiber slows gastric emptying and promotes satiety, and thus may help to regulate appetite. Dietary fiber may decrease the rate of release and absorption of simple sugars, and help in the regulation of blood sugar, with lower postprandial blood sugars observed. Dietary fiber has a low glycemic index, and may have a beneficial effect on insulin sensitivity. Fiber also binds luminal cholesterol and reduces absorption and/or enterohepatic circulation of the cholesterol in bile salts (with the intake of more viscous forms of dietary fiber, such as pectin). Soluble fiber types (such as guar gum, oat products, pectin) lower serum cholesterol, while insoluble fiber may reduce serum triglycerides. However, fiber such as psyllium, resistant dextrins, and resistant starch may also have a role in lowering both serum LDL and triglycerides. Decreased fiber intake in Western society has been associated with the increasing incidence and prevalence of diabetes, obesity, cardiovascular disease, colon cancer, and inflammatory bowel disease.

Data are insufficient to establish an EAR for dietary fiber. An AI for dietary fiber has been established based on the intake levels associated with reducing risk for cardiovascular disease and in lowering or normalizing serum cholesterol (see Table 44-3). An UL has not been established for fibers, which are not thought to be harmful to human health. A general rule of thumb used for fiber intake in children is: *age (in years) + 5 = grams of fiber intake per day*.

MICRONUTRIENTS

Vitamins and trace minerals or **micronutrients** play an essential role in growth and development and contribute to a host of physiologic functions. Many U.S. children have suboptimal intake of iron, zinc, potassium, calcium, vitamin D, and vitamin K, and excess intakes of sodium. Dietary recommendations for micronutrients were originally established to prevent deficiency but also include the impact of micronutrients on long-term health outcomes (Table 44-5). Food fortification is an effective strategy to prevent some nutrient deficiencies, and

Note: Starred numbers are AI, and bold numbers are RDA. RDAs and AIs may both be used as goals for individual intake. RDAs are set to meet the needs of 97-98% of members in a group. For healthy breast-fed infants, the AI is the mean intake. The AI for other life stage and gender groups is believed to cover the needs of all members of the group, but lack of data prevents specifying with confidence the percentage covered by this intake.

UL is the maximum level of daily nutrient intake that is likely to pose no risk of adverse effects. Unless otherwise specified, the UL represents total intake from food, water, and supplements. Because of a lack of suitable data, ULs could not be established for potassium, water, and inorganic sulfate. In the absence of ULs, extra caution may be warranted in consuming levels above recommended intakes.

ND amounts are not determinable because of a lack of data of adverse effects in this age group and concern with regard to lack of ability to handle excess amounts. Source of intake should be from food only to prevent high levels of intake.

*Adequate intake. *RDA for vitamin D in IU/day: 400 if <1 yr age, 600 if >1 yr, lactating, or pregnant.

AI, adequate intake; GI, gastrointestinal; ND, not determinable; PLP, pyridoxal phosphate; PMP, pyridoxamine phosphate; PNP, pyridoxine phosphate; RDA, recommended dietary allowance; UL, upper limit.

Adapted from Food and Nutrition Board, Institute of Medicine: Dietary reference intakes for calcium, phosphorous, magnesium, vitamin D, and fluoride *(website),* www.nap.edu/openbook.php?record_id=5776; Dietary reference intakes for thiamin, riboflavin, niacin, vitamin B6, folate, vitamin B12, pantothenic acid, biotin, and choline *(website),* www.nap.edu/openbook.php?record_id=6015; Dietary reference intakes for vitamin C, vitamin E, selenium, and carotenoids *(website),* www.nap.edu/openbook.php?record_id=9810; *and* Dietary reference intakes for vitamin A, vitamin K, arsenic, boron, chromium, copper, iodine, iron, manganese, molybdenum, nickel, silicon, vanadium, and zinc *(website),* www.nap.edu/openbook.php?record_id=10026.

has been successfully implemented to prevent iodine and folate deficiency.

Breast milk provides optimal intake of most nutrients including iron and zinc. Although they present in lower amounts than in infant formula, they are more bioavailable and sufficient to meet infant needs until ~4-6 mo of age. After 4-6 mo of age, iron and zinc are required from complementary foods, such as iron-fortified cereal and pureed meats.

Iron requirements are higher during infancy and childhood as compared to later life stages, and are higher for menstruating females as compared to males of similar age groups (see Chapter 54). Iron present in animal protein is more bioavailable than that found in vegetables and other foods because it is already incorporated into heme moieties in blood and muscle. Iron deficiency is the most common micronutrient deficiency and is associated with iron-deficiency anemia and neurocognitive deficits. **Zinc** deficiency affects millions of children and is associated with increased risk for impaired linear growth (stunting), impaired immune function, and increased risk for respiratory and diarrheal diseases.

Breast milk is a poor source of **vitamin D** (see Chapter 51). Vitamin D insufficiency is more common than previously thought in infants and children. Vitamin D is central to calcium and bone metabolism, but is also an important determinant of various nonosseous health outcomes. Vitamin D is absorbed in the skin from sunlight and is also present naturally in some foods and fortified in all cow milk products, regardless of fat content, soy milk, almond milk, and orange juice. Sunlight exposure varies by season. Therefore, for populations residing in northern latitudes and/or who have darker skin, sunlight exposure is unlikely to meet the vitamin D needs over the year; in these groups, additional sunlight exposure and/or vitamin D supplementation may be required to achieve optimal status.

Children with darker skin and those who do not consume fortified products should be screened for vitamin D deficiency. The DRI for vitamin D is based on its effects on calcium status and bone health. The goal is to achieve serum levels of 25(OH) D levels above 50 nmol/L (30 ng/dL), which is often achieved using vitamin D supplementation. In 2010, the American Academy of Pediatrics increased total vitamin D intake recommendations to 600 IU/day for infants and children. A supplement was recommended for all breast-fed infants to ensure sufficient intake.

Calcium adequacy is determined in part as a function of bone health as measured by bone mineral content and density. The main storage organs for calcium are the bones and teeth. Bone mineral accretion occurs primarily in the pediatric age range, with peak bone mass being achieved by the 2nd to 3rd decade of life. Calcium recommendations vary by age and were also increased from AI to RDA, and the UL was increased in 9-18 yr olds (Table 44-6).

Vitamin K is an important determinant of bone health, but is also an important cofactor for coagulation factors (factors II, VII, IX, and X; protein C; and protein S) (see Chapter 53). Status can be assessed by prothrombin time, protein in the absence of vitamin K (PIVKA-II) and the vitamin K–dependent coagulation factor levels. Neonates are at risk for suboptimal vitamin K status, leading to an increased risk for hemorrhagic disease of the newborn. Vitamin K prophylaxis at birth is recommended for all newborn infants.

Potassium and sodium are the main intra- and extracellular cations, respectively, and are involved in transport of fluids and nutrients across the cellular membrane. There is an AI set for **potassium** related to its effects in maintaining a healthy blood pressure, reducing risk for nephrolithiasis, and supporting bone health. Moderate potassium deficiency can occur even in the absence of hypokalemia and can result in increased blood pressure, stroke, and other cardiovascular disease. Most American children have potassium intake below the current recommendations. African-Americans in particular are at increased risk for potassium deficiency. For people at increased risk for hypertension and who are salt sensitive, reducing sodium intake and increasing potassium intake is advised. Leafy green vegetables, vine fruit (such as tomatoes) and root vegetables are good food sources of potassium (see Table 44-6). People with impaired renal function may need to reduce potassium intake as hyperkalemia can increase risk for fatal cardiac arrhythmias among these patients.

Sodium has an AI, but given the risk of hypertension, an UL has also been set. The UL threshold may be even lower in African-Americans, who, on average, are more salt sensitive, and for those with hypertension or preexisting renal disease. Dietary sodium intake also displaces potassium intake. Elevated sodium: potassium ratios can increase the risk for nephrolithiasis. Intakes of <2,300 mg (approximately 1 tsp) per day are recommended. The average daily salt intake for most people in the United States and Canada exceeds both the AI and UL. Most dietary salt in the United States is found in processed foods, breads, condiments, and as a food preservative, and to enhance palatability. *For populations with or at risk for hypertension and renal disease, sodium intake should be decreased to <1,500 mg/day and potassium intake increased to >4,700 mg/day.* For persons with hypertension, additional dietary guidelines are available from the Dietary Approaches to Stop Hypertension (DASH) eating plan.

WATER

The water requirement and content as a proportion of body weight are highest in infants and decrease with age. Water intake is achieved with liquid and food intake, and losses include excretion in the urine and stool as well as insensible and evaporative losses through the skin and respiratory tract. An AI has been established for water (see Table 44-6). Special considerations are required by life stages and by basal metabolic rate, physical activity, body proportions (surface area to volume), environment, and underlying medical conditions. Breast milk and infant formula provide adequate water, and additional water intake is not required until complementary foods are introduced. Although water contains no calories, the concern is that water intake might actually decrease breast milk intake and displace the intake of essential nutrients during this metabolically very active life stage. The increased fluid needs of infants and young children can be explained in part by the high ratio of body surface area to volume in infancy and high respiratory rate.

The consequences of inadequate fluid intake include dehydration, impaired thermoregulation and heat dissipation, reduced activity tolerance and performance, and reduced intravascular fluid. These deficits can result in an increased compensatory heart rate, hypotension and syncope, and, if uncorrected, renal injury or nephrolithiasis. Excess free water intake is usually better tolerated by healthy adults than by younger children, who may be at increased risk for water intoxication. Hyponatremia can result from excess free water intake coupled with inadequate sodium intake. Fluid intake requirements and restrictions are also influenced by underlying renal and hormonal disorders, including diabetes, the syndrome of inappropriate antidiuretic hormone secretion, and diabetes insipidus.

MEASURING NUTRITIONAL ADEQUACY

Growth according to expected patterns can be tracked using the 2000 Centers for Disease Control and Prevention (CDC) and 2006 WHO growth charts (see Chapters 6 and 15). The WHO growth charts are derived from longitudinal and cross-sectional data obtained from a sample of healthy breast-fed infants and children (0-5 yr) who were receiving adequate nutritional intake and medical care from Brazil, Ghana, India, Norway, Oman, and the United States. Consequently, the WHO growth charts are not only descriptive of population average and distribution, but are also prescriptive regarding how adequately nourished healthy children under best-care practices should grow. The CDC and American Academy of Pediatrics recommend the use of the WHO charts to monitor growth of all infants and children (breast and bottle or infant formula fed) from birth to 2 yr of age, and the use of the CDC 2000 growth charts for children 2 to 20 yr of age.

Although the WHO and CDC growth charts are recommended for growth and nutritional assessment, a number of disease-specific charts are available. It is noteworthy that many other disease- or syndrome-specific growth charts are based on small samples of children, and include children with suboptimal nutritional status. For these patient

		9-13 yr	2.1				
		14-18 yr	2.3				
		≥19 yr	2.7				
		Pregnancy (L/day)					
		≥14 yr	3.0				
		Lactation (L/day)					
		≥14 yr	3.8				

Note: Bold numbers are RDA. RDAs and AIs may both be used as goals for individual intake. RDAs are set to meet the needs of 97-98% of members in a group. For healthy breast-fed infants, the AI is the mean intake. The AI for other life-stage and gender groups is believed to cover the needs of all members of a group, but lack of data prevents specifying with confidence the percentage covered by this intake. UL is the maximum level of daily nutrient intake that is likely to pose no risk of adverse effects. Unless otherwise specified, the UL represents total intake from food, water, and supplements. Because of a lack of suitable data, ULs could not be established for potassium, water, and inorganic sulfate. In the absence of ULs, extra caution may be warranted in consuming levels above recommended intakes. ND amounts are not determinable because of a lack of data on adverse effects in this age group and concern with regard to lack of ability to handle excess amounts. Source of intake should be from food only to prevent high levels of intake.

*Vitamin D RDA in IU/day: 40 if <1 yr, 600 if >1 yr of age or pregnant or lactating.

ACE, angiotensin-converting enzyme; AI, adequate intake; ARB, angiotensin receptor blocker; GI, gastrointestinal; ND, not determinable; RDA, recommended dietary allowance; UL, upper limit.

Adapted from Food and Nutrition Board, Institute of Medicine: Dietary reference intakes for water, potassium, sodium, chloride, and sulfate *(website). http://www.nap.edu/openbook.php?record_id=10925.*

groups, disease-specific charts may be helpful to use in conjunction with the WHO or CDC growth charts for comparison to children of similar age and sex from the general population. The goal should be to use this information to approximate growth as closely to that of the general population as possible in these subsets of children, where and when possible. In addition to anthropometry, other nutrient biomarkers can be used to assess status. For infants and children with specific dietary or health concerns, consultation with lactation consultants, registered dieticians, and/or physician nutrition specialists may also be indicated.

Chapter 45

Feeding Healthy Infants, Children, and Adolescents

Elizabeth P. Parks, Ala Shaikhkhalil, Veronique Groleau, Danielle Wendel, and Virginia A. Stallings

Early nutrition plays an important role in the origin of adult diseases such as type 2 diabetes, hypertension, obesity, and the metabolic syndrome; therefore, appropriate feeding practices should be established in the neonatal period and continued throughout childhood and adolescence to adulthood. Healthy feeding in children requires partnerships between family members, the healthcare system, schools, the community, and the government.

FEEDING DURING THE FIRST YEAR OF LIFE

Breastfeeding

The American Academy of Pediatrics (AAP) and World Health Organization (WHO) have declared breastfeeding and the administration of human milk to be the normative practice for infant feeding and nutrition. Breastfeeding has documented short- and long-term medical and neurodevelopmental advantages (Tables 45-1 and 45-2) and rare contraindications (Table 45-3). Thus the decision to breastfeed should be considered a public health issue and not only a lifestyle choice. The AAP and the WHO recommend that infants should be exclusively breastfed or given breast milk for 6 months. Breastfeeding should be continued with the introduction of complementary foods for 1 year or longer, as mutually desired by mother and infant. The success of breastfeeding initiation and continuation depends on multiple factors, such as education about breastfeeding, hospital breastfeeding practices and policies, routine and timely follow-up care, and family and societal support (Table 45-4).

Feedings should be initiated soon after birth unless medical conditions preclude them. Mothers should be encouraged to nurse at each breast at each feeding starting with the breast offered second at the last feeding. It is not unusual for an infant to fall asleep after the first breast and refuse the second. It is preferable to empty the first breast before offering the second in order to allow complete emptying of both breasts and therefore better milk production. Table 45-5 summarizes patterns of milk supply in the 1st week.

New mothers should be instructed about infant hunger cues, correct nipple latch, positioning of the infant on the breast, and feeding frequency. It is also suggested that someone trained in lactation observe a feeding to evaluate positioning, latch, milk transfer and maternal responses, and infant satiety. Attention to these issues during the birth hospitalization allows dialogue with the mother and family and can prevent problems that could occur with improper technique or knowledge of breastfeeding. As part of the discharge teaching process, issues surrounding infant feeding, elimination patterns, breast engorgement, basic breast care, and maternal nutrition should be discussed. A follow-up appointment is recommended within 24-48 hr after hospital discharge.

Table 45-1 Selected Beneficial Properties of Human Milk Compared to Infant Formula

Secretory IgA	Specific antigen-targeted antiinfective action
Lactoferrin	Immunomodulation, iron chelation, antimicrobial action, antiadhesive, trophic for intestinal growth
κ-Casein	Antiadhesive, bacterial flora
Oligosaccharides	Prevention of bacterial attachment
Cytokines	Antiinflammatory, epithelial barrier function
Growth factors	
Epidermal growth factor	Luminal surveillance, repair of intestine
Transforming growth factor (TGF)	Promotes epithelial cell growth (TGF-β) Suppresses lymphocyte function (TGF-β)
Nerve growth factor	Promotes neural growth
Enzymes	
Platelet-activating factor-acetylhydrolase	Blocks action of platelet-activating factor
Glutathione peroxidase	Prevents lipid oxidation
Nucleotides	Enhance antibody responses, bacterial flora

Adapted from Hamosh M: Bioactive factors in human milk, Pediatr Clin North Am *48:69–86, 2001.*

Table 45-2 Conditions for Which Human Milk Has Been Suggested to Possibly Have a Protective Effect

Acute disorders	Crohn disease
Diarrhea	Childhood cancer
Otitis media	Lymphoma
Urinary tract infection	Leukemia
Necrotizing enterocolitis	Recurrent otitis media
Septicemia	Allergy
Infant botulism	Obesity and overweight
Insulin-dependent diabetes mellitus	Hospitalizations
Celiac disease	Infant mortality

Nipple Pain

Nipple pain is one of the most common complaints of breastfeeding mothers in the immediate postpartum period. Poor infant positioning and improper latch are the most common reasons for nipple pain beyond the mild discomfort felt early in breastfeeding. If the problem persists and the infant refuses to feed, consideration needs to be given to nipple candidiasis. If present the mother should be treated with an antifungal cream that is wiped away before feeding, and the infant treated with oral medication.

Engorgement

In the second stage of lactogenesis, physiologic fullness of the breast occurs. Breasts may become engorged: firm, overfilled, and painful as the pattern and volume of milk production is adjusting to the infant's feeding schedule. Incomplete removal of milk as a result of poor breastfeeding technique or infant illness can cause engorgement. Breastfeeding immediately at signs of infant hunger will eventually prevent this

Table 45-3 Absolute and Relative Contraindications to Breastfeeding Because of Maternal Health Conditions

MATERNAL HEALTH CONDITION	DEGREE OF RISK
HIV and HTLV infection	In the United States, breastfeeding is contraindicated In other settings, health risks of not breastfeeding must be weighed against the risk of transmitting virus to the infant
Tuberculosis infection	Breastfeeding is contraindicated until completion of approximately 2 wk of appropriate maternal therapy
Varicella-zoster infection	Infant should not have direct contact to active lesions Infant should receive immune globulin
Herpes simplex infection	Breastfeeding is contraindicated with active herpetic lesions of the breast
CMV infection	May be found in milk of mothers who are CMV seropositive Transmission through human milk causing symptomatic illness in term infants is uncommon
Hepatitis B infection	Infants routinely receive hepatitis B immune globulin and hepatitis B vaccine if mother is HbsAg positive No delay in initiation of breastfeeding is required
Hepatitis C infection	Breast-feeding is not contraindicated
Alcohol intake	Limit maternal alcohol intake to <0.5 g/kg/day (for a woman of average weight, this is the equivalent of 2 cans of beer, 2 glasses of wine, or 2 oz of liquor)
Cigarette smoking	Discourage cigarette smoking, but smoking is not a contraindication to breastfeeding
Chemotherapy, radiopharmaceuticals	Breastfeeding is generally contraindicated

CMV, cytomegalovirus; HbsAg, hepatitis B surface antigen; HIV, human immunodeficiency virus; HTLV, human T-lymphotropic virus.

Data from Schanler RJ, Krebs NF, Mass SB (eds): Breastfeeding handbook for physicians, *ed 2, Elk Grove Village, IL, 2014, American Academy of Pediatrics, pp 223–226.*

from occurring. To reduce engorgement, breasts should be softened prior to infant feeding with a combination of hot compresses and expression of milk. Between feedings a supportive bra should be worn, cold compresses applied, and oral nonsteroidal antiinflammatory medications administered.

Mastitis

Mastitis occurs in 2-3% of lactating women and is usually unilateral, manifesting with localized warmth, tenderness, edema, and erythema after the second postdelivery week. Sudden onset of breast pain, myalgia, and fever with fatigue, nausea, vomiting, and headache can also occur. Organisms implicated in mastitis include *Staphylococcus aureus, Escherichia coli,* group A streptococcus, *Haemophilus influenzae, Klebsiella pneumoniae,* and *Bacteroides* spp. Diagnosis is confirmed by physical examination. Oral antibiotics and analgesics, while promoting breastfeeding or emptying of the affected breast, usually resolve the infection. A breast abscess is a less common complication of mastitis, but it is a more serious infection that requires intravenous antibiotics, incision, and drainage, along with temporary cessation of feeding from that breast.

Table 45-4 Recommendations on Breastfeeding Management for Healthy Term Infants

1. Exclusive breastfeeding for about 6 months
   - Breastfeeding preferred; alternatively expressed mother's milk, or donor breast milk
   - To continue for at least the first year and beyond as long as mutually desired by mother and child
   - Complementary foods rich in iron and other micronutrients should be introduced at about 6 mo of age
2. Peripartum policies and practices that optimize breastfeeding initiation and maintenance should be compatible with the AAP and Academy of Breastfeeding Medicine Model Hospital Policy and include the following:
   - Direct skin-to-skin contact with mothers immediately after delivery until the first feeding is accomplished and encouraged throughout the postpartum period
   - Delay in routine procedures (weighing, measuring, bathing, blood tests, vaccines, and eye prophylaxis) until after the first feeding is completed
   - Delay in administration of intramuscular vitamin K until after the first feeding is completed but within 6 hr of birth
   - Ensure 8-12 feedings at the breast every 24 hr
   - Ensure formal evaluation and documentation of breastfeeding by trained caregivers (including position, latch, milk transfer, examination) at least once for each nursing shift
   - Give no supplements (water, glucose water, commercial infant formula, or other fluids) to breastfeeding newborn infants unless medically indicated using standard evidence-based guidelines for the management of hyperbilirubinemia and hypoglycemia
   - Avoid routine pacifier use in the postpartum period
   - Begin daily oral vitamin D drops (400 IU) at hospital discharge
3. All breastfeeding infants should be seen by a pediatrician within 48 to 72 hr after discharge from the hospital
   - Evaluate hydration (elimination patterns)
   - Evaluate body weight gain (body weight loss no more than 7% from birth and no further weight loss by day 5: assess feeding and consider more frequent follow-up)
   - Discuss maternal/infant issues
   - Observe feeding
4. Mother and infant should sleep in proximity to each other to facilitate breastfeeding
5. Pacifier should be offered, while placing infant in back-to-sleep-position, no earlier than 3 to 4 weeks of age and after breastfeeding has been established

From American Academy of Pediatrics: Breast-feeding and the use of human milk, Pediatrics *129:e827–e841, 2012.*

Inadequate Milk Intake

Insufficient milk intake, dehydration, and jaundice in the infant can become evident within the first week of life. Signs of insufficient milk intake include: lethargy, delayed stooling, decreased urine output, weight loss >7% of birth weight, hypernatremic dehydration, inconsolable crying and increased hunger. Insufficient milk intake may be caused by insufficient milk production, failure of established breastfeeding, and health conditions in the infant that prevent proper breast stimulation. Parents should be counseled that breastfed neonates feed 8-12 times a day with a minimum of 8 times per day. Careful attention to prenatal history can identify maternal factors that may be associated with this problem (failure of breasts to enlarge during pregnancy or within the first few days after delivery). Direct observation of breastfeeding can help identify improper technique. If a large volume of milk is expressed manually after breastfeeding, then the infant might not be extracting enough milk, eventually leading to decreased milk output. Late preterm infants (34-36 wk) are at risk for insufficient milk syndrome because of poor suck and swallow patterns or medical issues.

Jaundice

Breastfeeding jaundice is a common reason for hospital readmission of healthy breastfed infants and is largely related to insufficient fluid

Table 45-5 Patterns of Milk Supply

DAY OF LIFE	MILK SUPPLY
Day 1	Some milk (~5 mL) may be expressed
Days 2-4	Lactogenesis, milk production increases
Day 5	Milk present, fullness, leaking felt
Day 6 onward	Breasts should feel “empty” after feeding

Adapted from Neifert MR: Clinical aspects of lactation: promoting breastfeeding success, Clin Perinatol *26:281–306, 1999.*

intake during the first week of life (see Chapter 102.3). It may also be associated with dehydration and hypernatremia. **Breast milk jaundice** is a different disorder that causes persistently high serum indirect bilirubin in a thriving healthy baby that becomes evident later than breastfeeding jaundice, but which generally declines in the 2nd to 3rd wk of life. Infants with severe or persistent jaundice should be evaluated for other medical causes (see Chapter 102.3) before ascribing the jaundice to breast milk that might contain inhibitors of glucuronyl transferase or enhanced absorption of bilirubin from the gut. Persistently high bilirubin levels may require changing from breast milk to infant formula for 24-48 hr and/or treatment with phototherapy without cessation of breastfeeding. Breastfeeding should resume after the decline in serum bilirubin. Parents should be reassured and encouraged to continue collecting breast milk during the period when the infant is taking formula.

Collecting Breast Milk

The pumping of breast milk is a common practice when the mother and baby are separated for work, illness, or hospitalization of mother or infant. Good hand washing and hygiene should be emphasized. Electric breast pumps are more efficient and better tolerated by mothers than mechanical pumps or manual expression. Collection kits should be cleaned with hot soapy water, rinsed, and air dried after each use. Glass or plastic containers should be used to collect the milk, and milk should be refrigerated and then used within 48 hr. Expressed breast milk can be frozen and used for up to 6 mo. Milk should be thawed rapidly by holding under running tepid water and used completely within 24 hr after thawing. *Milk should never be microwaved.*

Growth of the Breastfed Infant

The rate of weight gain of the breastfed infant differs from that of the formula-fed infant, and the infant’s risk for excess weight gain during late infancy may be associated with bottle feeding. The WHO growth charts are based on the growth of healthy breastfed infants through the 1st yr of life. These standards (http://www.who.int/childgrowth) are the result of a study in which >8,000 children were selected from 6 countries. The infants were selected based on healthy feeding practices (breastfeeding), good health care, high socioeconomic status, and nonsmoking mothers, so that they reflect the growth of breastfed infants in the optimal conditions and can be used as prescriptive rather than normative curves. Charts are available for growth monitoring from birth to age 6 yr. The Centers for Disease Control and Prevention (CDC) recommends use of the WHO growth charts for infants 0-23 months of age, and CDC growth charts for ages 24 mo to 20 yr.

Formula Feeding (Fig. 45-1)

Despite efforts to promote exclusive breastfeeding through 6 months, less than 50% of women continue to breastfeed at 6 months. Most women make their infant feeding choices early in pregnancy. Parental preference is the most common reason for using infant formula. However, infant formula is also indicated in infants whose intake of breast milk is contraindicated for infant factors (e.g. inborn errors of metabolism), and maternal factors (see Table 45-3). In addition infant formula is used as a supplement to support inadequate weight gain in breastfed infants.

Infant formulas marketed in the United States are safe and nutritionally adequate as the sole source of nutrition for healthy infants for the first 6 months of life. Infant formulas are available in ready-to-feed, concentrated liquid or powder forms. Ready-to-feed products generally provide 20 kcal/30 mL (1 oz) and approximately 67 kcal/dL. Concentrated liquid products, when diluted according to instructions, provide a preparation with the same concentration. Powder formulas come in single or multiple servings and when mixed according to instructions will result in similar caloric density.

Although infant formulas are manufactured in adherence to good manufacturing practices and are regulated by the U.S. Food and Drug Administration (FDA), there are still potential safety issues. Powder preparations are not sterile, and although the number of bacterial colony-forming units per gram of formula is generally lower than allowable limits, outbreaks of infections with *Enterobacter sakazakii* have been documented, especially in premature infants. The powder preparations can contain other coliform bacteria but have not been linked to disease in healthy term infants. Care must be taken in following the mixing instructions to avoid over- or underdilution, to use boiled or sterilized water, and to use the specific scoops provided by the manufacturer as scoop sizes vary. Water that has been boiled should be allowed to cool fully to prevent degradation of heat labile nutrients, specifically vitamin C. Well water should be tested regularly for bacteria and toxin contamination. Municipal water can contain variable concentrations of fluoride, and if the concentrations are high, bottled water that is defluoridated should be used to avoid toxicity.

Parents should be instructed to use proper handwashing techniques when preparing formula and feedings for the infant. Guidance to follow written instructions for storage should also be given. Once opened, ready-to-feed and concentrated liquid containers can be covered with aluminum foil or plastic wrap and stored in the refrigerator for no longer than 48 hr. Powder formula should be stored in a cool, dry place; once opened, cans should be covered with the original plastic cap or aluminum foil, and the powdered product can be used within 4 weeks. Once prepared, all bottles regardless of type of formula should be used within 24 hours. Formula should be used within 2 hours of removal from the refrigerator and once a feeding has started, that formula should be used within an hour or be discarded. Prepared formula stored in the refrigerator should be warmed by placing the container in warm water for ~5 min. Formula should not be heated in a microwave, because it can heat unevenly and result in burns despite appearing to be at the right temperature when tested.

Formula feedings should be ad libitum, with the goal of achieving growth and development to the child’s genetic potential. The usual intake to allow a weight gain of 25-30 g/day will be 140-200 mL/kg/day in the first 3 months of life. The rate of weight gain declines from 3-12 months of age.

COW MILK PROTEIN–BASED FORMULAS

Intact cow milk–based formulas in the United States contain a protein concentration varying from 1.8 to 3 g/100 kcal or (1.45-1.6 g/dL), considerably higher than in mature breast milk (1.5 g/100 kcal). This increased concentration is designed to meet the needs of the youngest infants but leads to excess protein intake for older infants. In contrast, breastfed infants receive protein intakes that match their needs at various ages. The whey : casein ratio varies from 18 : 82 to 60 : 40; one manufacturer markets a formula that is 100% whey. The predominant whey protein is β-globulin in cow milk and α-lactalbumin in human milk. This and other differences between human milk and cow milk–based formulas result in different plasma amino acid profiles in infants on different feeding patterns, but a clinical significance of these differences has not been demonstrated.

Plant or a mixture of plant and animal oils are the source of fat in infant formulas; fat provides 40-50% of the energy in cow milk–based formulas. Fat blends are better absorbed than dairy fat and provide saturated, monounsaturated, and polyunsaturated fatty acids (PUFAs). All infant formulas are supplemented with long-chain PUFAs, docosahexaenoic acid (DHA), and arachidonic acid (ARA) at varying

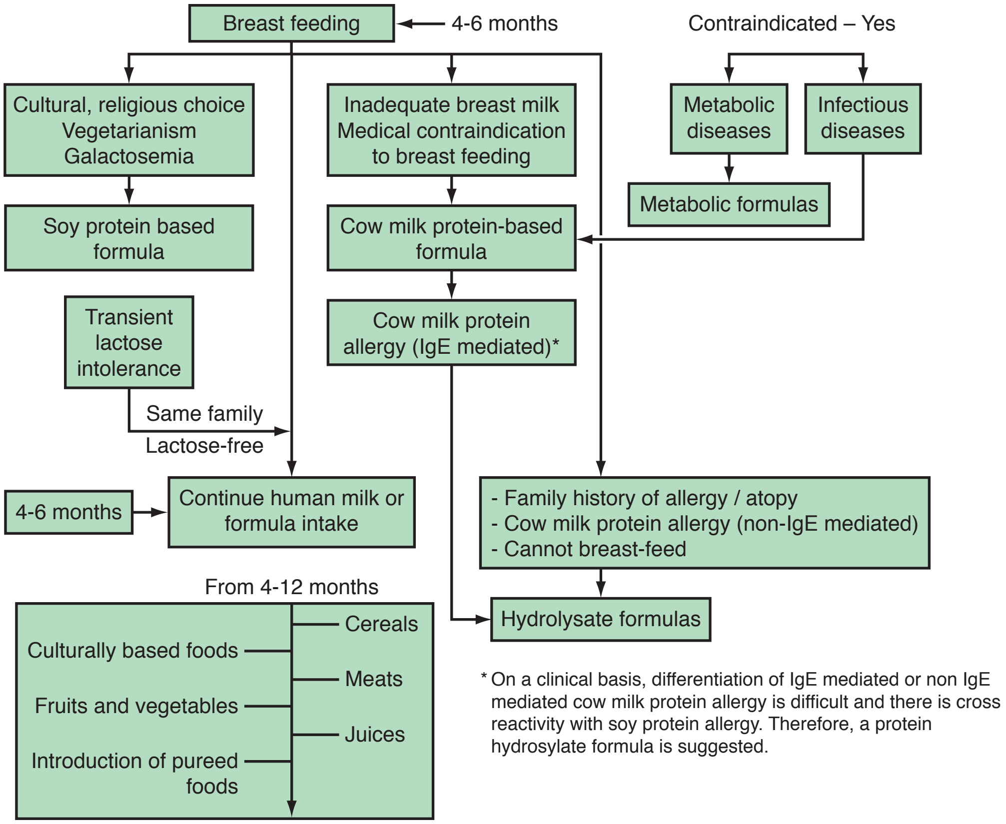

Figure 45-1 Feeding algorithm for term infants. *(From Gamble Y, Bunyapen C, Bhatia J: Feeding the term infant. In Berdanier CD, Dwyer J, Feldman EB, editors:* Handbook of nutrition and food, *Boca Raton, FL, 2008, CRC Press, pp 271–284,* Fig. 15-3.*)*

concentrations. ARA and DHA are found at varying concentrations in human milk and vary by geographic region and maternal diet. No studies in term infants have found a negative effect of DHA and ARA supplementation, and some studies have demonstrated positive effects on visual acuity and neurocognitive development. A critical review concluded that there are no consistent effects of long-chain PUFAs on visual acuity in term infants. A Cochrane review concluded that routine supplementation of milk formula with long chain PUFAs to improve the physical, neurodevelopmental, or visual outcomes of term infants cannot be recommended based on the current evidence. DHA and ARA are derived from single-cell microfungi and microalgae and are classified as generally recognized as safe for use in infant formulas at approved concentrations and ratios.

Lactose is the major carbohydrate in breast milk and in standard cow milk–based formulas for term infants. Formulas for term infants may also contain modified starch or other complex carbohydrates. Carbohydrates comprise 69-75g/L of cow milk–based formula.

SOY FORMULAS

Soy protein–based formulas on the market are all free of cow milk–based protein and lactose and use sucrose, corn syrup solids, and/or maltodextrin to provide 67 kcal/dL. They meet the vitamin, mineral, and electrolyte guidelines from the AAP and the FDA for feeding term infants. The protein is a soy isolate supplemented with L-methionine, L-carnitine, and taurine to provide a protein content of 2.45-2.8 g per 100 kcal or 1.7-1.8 g/dL.

The quantity of specific fats varies by manufacturer and is usually similar to the manufacturer's corresponding cow milk–based formula. The fat content is 5.0-5.5 g per 100 kcal or 3.4-3.6 g/dL. The oils used in both cow milk and soy formula include soy, palm, sunflower, olein, safflower, and coconut. DHA and ARA are also added.

In term infants, although soy protein–based formulas have been used to provide nutrition resulting in normal growth patterns, there are few indications for use in place of cow milk–based formula. Indications for soy formula include galactosemia and hereditary lactase deficiency, because soy–based formulas are lactose-free; and situations in which a vegetarian diet is preferred. Most healthy infants with acute gastroenteritis can be managed after rehydration with continued use of breast milk or cow–based formulas and do not require a lactose-free formula, such as soy-based formula. However, soy protein–based formulas may be indicated when documented secondary lactose intolerance occurs. Soy protein–based formulas have no advantage over cow protein–based formulas as a supplement for the breastfed infant, unless the infant has one of the indications noted previously and are not recommended for preterm infants. The routine use of soy protein–based formula has no proven value in the prevention or management of infantile colic, fussiness, or atopic disease. Infants with documented cow protein–induced enteropathy or enterocolitis often are also sensitive to soy protein and should not be given isolated soy protein–based formula. They should be provided formula derived from extensively hydrolyzed protein or synthetic amino acids. Soy formulas contain phytoestrogens, which have been shown to have physiologic activity in rodent models but a meta-analysis of the topic done by the Center for the Evaluation of Risks to Human Reproduction concluded that there is minimal concern for adverse developmental effects in infants fed soy formula.

PROTEIN HYDROLYSATE FORMULA

Protein hydrolysate formulas may be *partially hydrolyzed*, containing oligopeptides with a molecular weight of <5000 Da, or *extensively hydrolyzed*, containing peptides with a molecular weight <3000 Da. Partially hydrolyzed proteins have fat blends similar to cow milk–based formulas, and carbohydrates are supplied by corn maltodextrin or corn syrup solids. Because the protein is not extensively hydrolyzed, these formulas should not be fed to infants who are allergic to cow protein. In studies of formula fed infants who are at high risk of developing

atopic disease there is modest evidence that childhood atopic dermatitis may be delayed or prevented by the use of extensively or partially hydrolyzed formulas, compared with cow milk–based formula. Comparative studies of the various hydrolyzed formulas have also indicated that not all formulas have the same protective benefit. Extensively hydrolyzed formulas may be more effective than partially hydrolyzed in preventing atopic disease. Extensively hydrolyzed formulas are recommended for infants intolerant to cow milk or soy proteins. These formulas are lactose free and can include medium-chain triglycerides, making them useful in infants with gastrointestinal malabsorption as a consequence of cystic fibrosis, short gut syndrome, prolonged diarrhea, and hepatobiliary disease.

AMINO ACID FORMULAS

Amino acid formulas are peptide-free formulas that contain mixtures of essential and nonessential amino acids. They are designed for infants with dairy protein allergy who failed to thrive on extensively hydrolyzed protein formulas. The effectiveness of amino acid formulas to prevent atopic disease has not been studied.

Milk and Other Fluids

Neither breastfed nor formula-fed infants require additional water unless dictated by high environmental temperature. Vomiting and spitting up are common in infants. When weight gain and general well-being are noted, no change in formula is necessary.

Whole cow milk should not be introduced until 12 mo of age. In children between 12 and 24 mo of age for whom being overweight or obesity is a concern or who have a family history of obesity, dyslipidemia, or cardiovascular disease, the use of reduced-fat milk is appropriate. Otherwise whole milk is recommended until age 24 months changing to 2% at 24 months, and 1% at 3 yr of age for healthy children. Regardless of the type, all milk consumed should be pasteurized. Infants and young children are particularly susceptible to infections such as *E. coli*, *Campylobacter*, and *Salmonella* found in raw or unpasteurized milk. For cultural and other reasons, such as parental preference, goat milk is sometimes given in place of formula although this is not recommended. Goat milk has been shown to cause significant electrolyte disturbances and anemia because it has low folic acid concentrations.

COMPLEMENTARY FEEDING

The timely introduction of complementary foods (solid and liquid foods other than breast milk or formula, also called weaning foods or beikost) during infancy is necessary to enable transition from milk feedings to other table foods and is important for nutritional and developmental reasons (Table 45-6). The ability of exclusive breastfeeding to meet macronutrient and micronutrient requirements becomes limiting with increasing age of the infant. The recommendation for timing of complementary feed initiation is based on the benefits on neurodevelopment and prevention of future comorbidities (see Table 45-2) from exclusive breastfeeding for 6 months. The AAP, WHO, and European Society for Pediatric Gastroenterology, Hepatology, and Nutrition Committee on Nutrition all recommend exclusive breastfeeding for the first 6 months. Similar data on the benefits of the exclusive use of formula for 6 months have not been published.

Some complementary foods are more nutritionally appropriate than others to complement breast milk or infant formula. The food consumption patterns of U.S. infants and toddlers demonstrate that nearly all infants ≤12 mo consumed some form of milk every day; infants >4 mo consumed more formula than human milk, and by 9-11 mo of age 20% consumed whole cow milk and 25% consumed nonfat or reduced-fat milk.

The most commonly fed complementary foods between 4 and 11 mo of age are infant cereals. Nearly 45% of infants between 9 and 11 mo of age consumed noninfant cereals. Infant eating patterns also vary, with up to 61% of infants 4-11 mo of age consuming no vegetables. Among those who consumed vegetables, French fries were the most common vegetables in toddlers. Positive changes in the last decade include increased duration of breastfeeding, delayed introduction of complementary foods, and decreased juice consumption. Continuing concerns included lack of fruits and vegetables, diets low in iron, essential fatty acids, fiber and whole grains, and high in saturated fat and sodium. Table 45-6 summarizes the AAP recommendations for initiating complementary foods.

The complementary foods should be varied to ensure adequate macro- and micronutrient intake. In addition to complementary foods introduced at 6 mo of age, continued breastfeeding or the use of infant formula for the entire 1st year of life should be encouraged. Overconsumption of energy-dense complementary foods can lead to excessive weight gain in infancy, resulting in an increased risk of obesity in childhood.

Table 45-6 Important Principles for Weaning
Begin at 6 mo of age
At the proper age, encourage a cup rather than a bottle
Introduce 1 food at a time
Energy density should exceed that of breast milk
Iron-containing foods (meat, iron-supplemented cereals) are required
Zinc intake should be encouraged with foods such as meat, dairy products, wheat, and rice
Phytate intake should be low to enhance mineral absorption
Breast milk should continue to 12 mo, formula or cow milk is then substituted
Give no more than 24 oz/day of cow milk
Fluids other than breast milk, formula, and water should be discouraged
Give no more than 4-6 oz/day of fruit juices; no sugar sweetened beverages

Adapted from American Academy of Pediatrics: Pediatric nutrition handbook, *ed 6, Elk Grove Village, IL, 2008, American Academy of Pediatrics.*

FEEDING TODDLERS AND PRESCHOOL-AGE CHILDREN

Toddlerhood is a period when eating behavior and healthful habits can be established and is often a confusing and anxiety-generating period. Growth after the 1st yr slows, motor activity increases, and appetite decreases. Birth weight triples during the 1st year of life and quadruples by 2 yr of age, reflecting this slowing in growth velocity. Eating behavior is erratic, and the child appears distracted as the child explores the environment. Children consume a limited variety of foods and often only "like" a particular food for a period of time and then reject the favored food. The use of growth charts to demonstrate adequate growth and to provide guidance about typical behavior and eating habits will help allay concerns of parents. Important goals of early childhood nutrition are to foster healthful eating habits and to offer foods that are developmentally appropriate.

Feeding Practices

The period starting after 6 mo until 15 mo is characterized by the acquisition of self-feeding skills because the infant can grasp finger foods, learn to use a spoon, and eat soft foods (Table 45-7). Around 12 mo of age, the child learns to drink from a cup and may still breastfeed or desire formula bottle feeding. Bottle weaning should begin around 12-15 mo and bedtime bottles should be discouraged because of the association with dental carries. Unless being used at mealtime, the sippy cup should only contain water to prevent caries. Sugar-sweetened beverages and 100% fruit juice should also be discouraged from being used in bottles in all infants at all times. Cups without a lid can be used for no more than 4-6 oz/day of 100% fruit juice for toddlers. In the 2nd year of life, self-feeding becomes a norm and provides the opportunity for the family to eat together with less stress. Self-feeding allows the child to limit the child's intake. Child feeding is an interactive process. Children receive cues regarding appropriate feeding behaviors from parents. Parents should ignore negative eating behaviors unless the behavior jeopardizes the health and safety of the child. In addition, parents should eat with their

Table 45-7 Feeding Skills Birth to 36 Months

AGE (mo)	FEEDING/ORAL SENSORIMOTOR
Birth to 4-6	Nipple feeding, breast, or bottle Hand on bottle during feeding (2-4 mo) Maintains semiflexed posture during feeding Promotion of infant–parent interaction
6-9 (transition feeding)	Feeding more in upright position Spoon feeding thin, pureed foods Both hands to hold bottle Finger feeding introduced Vertical munching of easily dissolvable solids Preference for parents to feed
9-12	Cup drinking Eats lumpy, mashed food Finger feeding for easily dissolvable solids Chewing includes rotary jaw action
12-18	Self-feeding; grasps spoon with whole hand Holds cup with 2 hands Drinking with 4-5 consecutive swallows Holding and tipping bottle
>18-24	Swallowing with lip closure Self-feeding predominates Chewing broad range food Up–down tongue movements precise
24-36	Circulatory jaw rotations Chewing with lips closed One-handed cup holding and open cup drinking with no spilling Using fingers to fill spoon Eating wide range of solid food Total self-feeding, using fork

Adapted from Arvedson JC. Swallowing and feeding in infants and young children. GI Motility online *(2006) doi:10.1038/gimo17.*

toddlers and not simply feed them in order to model positive eating behaviors.

The 2 yr old child should progress from small pieces of soft food to prepared table foods with precautions. At this stage, the child is not capable of completely chewing and swallowing foods, and particular attention should be paid to foods with a choking risk. Hard candies, nuts, and raw carrots should be avoided. Hot dogs, sausages, and grapes should be sliced length wise. Caregivers should always be vigilant and present during feeding, and the child should be placed in a high chair or booster seat. The AAP discourages eating in the presence of distractions such as television, tablets, mobile devices, and other screens, or eating in a car where an adult cannot adequately observe the child.

Young children have a natural preference for sweetened foods and beverages that begins in infancy. Reluctance to accept new foods is a common developmental phase. A new food should be offered multiple times (8-15) before being considered rejected by the child.

Toddlers need to eat 3 healthy meals and 2 snacks daily. Milk continues to be an important source of nutrition. Guidelines for vitamin D supplementation recommend a daily vitamin D intake of 600 IU/day for all infants beginning in the first few days of life, and for children and adolescents who are ingesting <1000 mL/day of vitamin D-fortified milk or formula. Toddlers and preschool children often fail to meet the recommended servings of fruits, vegetables, and fiber, whereas intakes of food with fat and added sugar are high. Giving vegetables at the beginning of the meal and increasing the portion size of vegetables served during meals can be an effective strategy for increasing vegetable consumption in preschool children.

Eating in the Daycare Setting

Many U.S. toddlers and preschool children attend daycare and receive meals and snacks in this setting. There is a wide variation in the quality

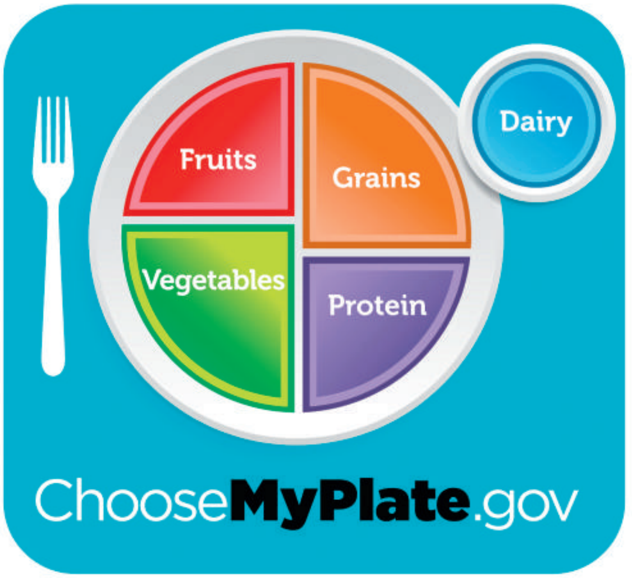

Figure 45-2 MyPlate food guide. *(From U.S. Department of Agriculture: mypyramid.gov. http://www.choosemyplate.gov/.)*

of the food offered and the level of supervision during meals. Parents are encouraged to assess the quality of the food served at daycare by asking questions, visiting the center, and taking part in parent committees. Free or reduced-price snacks and meals are provided in daycare centers for low- and medium-income communities through the U.S. Department of Agriculture (USDA) Child and Adult Care Food Program. Participating programs are required to provide meals and snacks that meet the meal regulations set by the USDA, guaranteeing a certain level of food quality. However, often for monetary reasons, many daycare centers still struggle to provide high-quality meals and snacks.

FEEDING SCHOOL-AGE CHILDREN AND ADOLESCENTS

MyPlate

The USDA MyPlate (www.choosemyplate.gov) is a basis for building an optimal diet for children and adults (Fig. 45-2). MyPlate is based on the *Dietary Guidelines for Americans, 2010* and replaces MyPyramid. MyPlate is aimed at the general public to provide a visual representation of the different food groups and their portion sizes. In addition to food group information, the website provides discretionary calorie information. It provides weight management strategies, and abilities to track calories and physical activity goals. A personalized eating plan based on these guidelines provide, on average over a few days, all the essential nutrients necessary for health and growth, while limiting nutrients associated with chronic disease development. MyPlate can also be used as an Internet interactive tool that allows customization of recommendations, based on age, sex, physical activity, and, for some populations, weight and height. Print material is also available for families without Internet access.

Recommendations based on MyPlate emphasize making half the plate vegetables and fruit, one half of the plate protein and grains, with protein having the smallest section. Protein replaces the meat category as many protein sources are not from animals. A separate dairy section is included. Physical activity recommendations to achieve a healthful energy balance are not visually displayed, but are provided on the website. MyPlate has removed foods that have low nutritional value, such as sweetened sugar beverages, and sweetened bakery products.

In the United States and in an increasing number of other countries, the vast majority of children and adolescents do not consume a diet that follows the recommendations of MyPlate. The intake of

discretionary calories is much higher than recommended, with frequent consumption of sweetened sugar beverages (soda, juice drinks, iced tea, sport drinks), snack foods, high-fat meat (bacon, sausage), and high-fat dairy products (cheese, ice cream). Intake of dark green and orange vegetables (as opposed to fried white potatoes), whole fruits, reduced-fat dairy products, and whole grain is typically lower than recommended. Furthermore, unhealthful eating habits such as larger-than-recommended portion sizes; food preparation that adds fat, sugar, or salt; skipping breakfast and/or lunch; grazing; or following fad diets is prevalent and associated with a poorer diet quality. MyPlate offers a helpful and customer-friendly tool to assist pediatricians counseling families on optimal eating plans for short- and long-term health.

Eating at Home

At home, much of what children and adolescents eat is under the control of their parents. Typically, parents shop for groceries and they control, to some extent, what food is available in the house. It has been demonstrated that modeling of healthful eating behavior by parents is a critical determinant of the food choices of children and adolescents. Counseling to improve diet should include guiding parents in using their influence to make healthier food choices available and attractive at home.

Regular family meals sitting at a table, as opposed to eating alone, in the living room, or watching television/screens, are associated with improved diet quality, perhaps because of increased opportunities for positive parenting during meals. Such an ideal situation is recommended but a challenge for many families who, with busy schedules and other stressors, are unable to provide such a setting. Another parenting challenge is to control the excess appetite of some children and adolescents. Encourage children to eat at a slower pace and to chew their food properly. Encourage conversation at the dinner table to prolong eating to 15 minutes. Offering vegetables while children are hungry at the beginning of the meal has been shown to increase vegetable consumption. Useful strategies, when the child is still hungry after a meal, include a 15- to 20-min pause (allow child to engage in another activity) before a second serving or offering foods that are insufficiently consumed, such as vegetables, whole grains, or fruits.

Eating at School

The National School Lunch Program and the School Breakfast Program provide low-cost meals to more than 5 billion children nationwide. Guidelines for meals are taken from the *Dietary Guidelines for Americans and the Dietary Reference, 2005*. Recommendations regarding the use of age-grade portion sizes, and amounts of vegetable and fruits, grains, and fats were included (Table 45-8). The training and equipment for school food service staff, school community engagement, parent education, and food industry involvement are among the necessary components. The year 2020 is the target year for achieving recommendations for sodium. In the meantime, while schools are working on implementing changes, parents should be encouraged to examine the weekly menu with their child and assist with their choices ahead of time. If children bring their lunch from home recommendations for what constitutes a healthy lunch should be provided by the Pediatrician. Parents can be directed to www.choosemyplate.org for healthy lunch ideas. In addition parties within classrooms should be limited to once a month.

Table 45-8 Revised National School Lunch Program and School Breakfast Program Recommendations

- Portion sizes of food are to be based on age-grade groups
- School lunches and breakfasts will have a minimum and maximum calorie level, maximum saturated fat content, and a maximum sodium content
- Foods must contain zero grams of trans fat per serving
- The inclusion of unsaturated vegetable oils is encouraged within calorie limits
- Vegetables and fruits are not interchangeable
- Vegetable offerings at lunch must include ½ cup equivalent of the following: dark green vegetables, bright orange vegetables, and legumes
- No more than half of fruit servings may be in the form of juice
- At least ½ of bread/grain offered must be whole grain
- Milk must be fat-free if flavored and either fat free or 1% if plain
- Students must select a fruit option at breakfast with their meal, and either a fruit or a vegetable at lunch for the meal to be reimbursable.

Adapted from IOM (Institute of Medicine): School meals: building blocks for healthy children. *Washington, DC, 2010, National Academies Press.*

Eating Out

The number of meals eaten outside the home or brought home from takeout restaurants has increased in all age groups of the U.S. population. The increased convenience of this meal pattern is undermined by the generally lower nutritional value of the meals, compared to home-cooked meals. Typically, meals consumed or purchased in fast-food or casual restaurants are of large portion size, are dense in calories, and contain large amounts of saturated fat, salt, and sugar, and low amounts of whole grains, fruits, and vegetables. Although still a problem currently, *trans* fat is slowing being phased out of most commercial restaurants. Although an increasing number of restaurants offer healthier alternatives, the vast majority of what is consumed at restaurants does not fit MyPlate.

With increasing age, an increasing number of meals and snacks are also consumed during peer social gatherings at friends' houses and parties. When a large part of a child's or adolescent's diet is consumed on these occasions, the diet quality can suffer, because food offerings are typically of low nutritional value. Parents and pediatricians need to guide teens in navigating these occasions while maintaining a healthful diet and enjoying meaningful social interactions. These occasions often are also opportunities for teens to consume alcohol; consequently, adult supervision is important.

NUTRITION ISSUES OF IMPORTANCE ACROSS PEDIATRIC AGES

Food Environment

Most families have some knowledge of nutrition and intend to provide their children with a healthful diet. The discrepancy between this fact and the actual quality of the diet consumed by U.S. children is often explained by challenges in the environment for families to make healthful food choices. Because the final food choice is made by individual children or their parents, interventions to improve diet have focused on individual knowledge and behavior changes, but have had limited success. A main determinant of food choice is taste, but other factors also influence these choices. One of the most useful conceptual frameworks for understanding the child's food environment in the context of obesity illustrates the variety of individual food and physical activity choices. Many of these determinants are not under the direct control of individual children or parents (Fig. 45-3). Understanding the context of food and lifestyle choices helps in understanding lack of changes or "poor compliance" and can decrease the frustration often experienced by the pediatricians who might "blame the victim" for behavior that is not entirely under their control.

Marketing and advertising of food to children is a particularly illustrative aspect of the food environment. Marketing includes strategies as diverse as shelf placements, association of cartoon characters with food products, coupons, and special offers or pricing, all of which influence food purchase choices. Television advertising is an important part of how children and adolescents hear about food, with an estimated 40,000 TV commercials per yr, seen by the average U.S. child, many of which are for food, as compared to the few hours of nutrition education they receive in school. Additional food advertisement increasingly occurs as brand placement in movies and TV shows, on websites, and even video games.

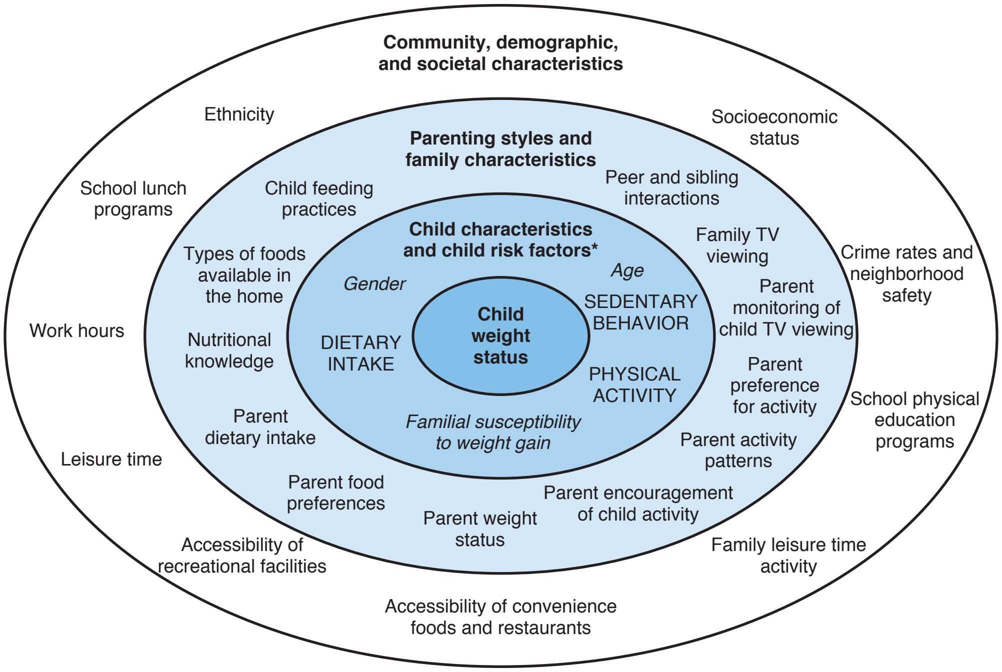

Figure 45-3 **A conceptual framework of the context of food and lifestyle choices.** Child risk factors (shown in uppercase lettering) refer to child behaviors associated with the development of overweight. Characteristics of the child (shown in italic lettering) interact with child risk factors and contextual factors to influence the development of overweight (i.e., moderator variables). *(From Davison KK, Birch LL: Childhood overweight: a contextual model and recommendations for future research,* Obes Rev *2:159–171, 2001. © 2001 The International Association for the Study of Obesity.)*

Using Food as Reward

It is a prevalent habit to use food as a reward or sometimes withdraw food as punishment. Most parents use this practice occasionally, and some use it almost systematically, starting at a young age. The practice is also commonly used in other settings where children spend time, such as daycare, school, or even athletic settings. Although it might be a good idea to limit some unhealthy but desirable food categories to special occasions, using food as a reward is problematic. Limiting access to some foods and making its access contingent on a particular accomplishment increases the desirability of that type of food. Conversely, encouraging the consumption of some foods renders them less desirable. Therefore, phrases such as "finish your vegetables, and you will get ice cream for dessert" can result in establishing unhealthy eating habits once the child has more autonomy in food choices. Parents should be counseled on such issues and encouraged to choose items other than food as reward, such as inexpensive toys or sporting equipment, family time, special family events, or collectable items. Similar types of behavior are also seen in schools and extra-curricular events. As opposed to rewarding or punishments of food (pizza/candy) daycare providers, teachers, and counselors should be encouraged to use alternative rewards such as minutes of free time, sitting in the teacher's chair, being the teacher helper, and homework-free nights.

Cultural Considerations in Nutrition and Feeding

Food choices, food preparation, eating patterns, and infant feeding practices all have very deep cultural roots. In fact, beliefs, attitudes, and practices surrounding food and eating are some of the most important components of cultural identity. Therefore, it is not surprising that in multicultural societies, great variability exists in the cultural characteristics of the diet. Even in a world where global marketing forces tend to reduce geographic differences in the types of food, or even brands, that are available, most families, especially during family meals at home, are still much influenced by their cultural background. Therefore, pediatricians should become familiar with the dietary characteristics of various cultures in their community, so that they can identify and address, in a nonjudgmental way and avoiding stereotypes, the potential nutritional issues related to the diet of their patients.

Vegetarianism

Vegetarianism is the practice of following a diet that excludes animal flesh foods, including beef, pork, poultry, fish, and shellfish. There are several variants of the diet, some of which also exclude eggs and/or some products produced from animal labor, such as dairy products and honey. There are many different variations in vegetarianism:

- Veganism: excludes all animal products. It may be part of a larger practice of abstaining from the use of animals products for any purpose.
- Ovovegetarianism: includes eggs but not dairy products.
- Lactovegetarianism: includes dairy products but excludes eggs.
- Lactoovovegetarianism: includes eggs and dairy products.
- Flexitarian: recent term referring to a vegetarian who will occasionally eat meat.

Another expression used for vegetarianism and veganism is "plant-based diets."

Other dietary practices commonly associated with vegetarianism include fruitarian diet (fruits, nuts, seeds, and other plant matter gathered without harm to the plant); Su vegetarian diet (a diet that excludes all animal products as well as onion, garlic, scallions, leeks, or shallots); a macrobiotic diet (whole grains and beans and, in some cases, fish); and raw vegan diet (fresh and uncooked fruits, nuts, seeds, and vegetables). The safety of these restrictive diets has not been studied in children. These diets can be very limited in macro- and micronutrients and are not recommended for children. Implementing vegetarian diets in teenage girls may be a sign of an eating disorder.

Vegetarianism is considered a healthful and viable diet; both the Academy of Nutrition and Dietetics (formerly the American Dietetic Association) and the Dietitians of Canada have found that a properly planned and well-balanced vegetarian diet can satisfy the nutritional

goals for all stages of life. Compared with nonvegetarian diets, vegetarian diets have low levels of saturated fat, cholesterol, and animal protein, and relatively higher levels of complex carbohydrates, fiber, magnesium, potassium, folate, vitamins C and E, and phytochemicals. Vegetarians have a lower body mass index, cholesterol, and blood pressure, and are at decreased risk for cancer and ischemic heart disease.

Specific nutrients of concern in vegetarian diets include:

- **Iron:** Vegetarian diets have similar levels of iron compared to nonvegetarian diets, but the iron has lower bioavailability than iron from meat sources, and iron absorption may be inhibited by other dietary constituents, such as phytate (see Chapter 54). Iron stores are lower in vegetarians and vegans than in nonvegetarians; and iron deficiency is more common in vegetarian and vegan women and children. Foods rich in iron include iron-fortified cereals, black beans, cashews, kidney beans, lentils, oatmeal, raisins, black-eyed peas, soybeans, sunflower seeds, chickpeas, molasses, chocolate, and tempeh.
- **Vitamin B_{12}:** Plants are not a good source of B_{12} (see Chapter 49.7). Additional vitamin B_{12} can be obtained through dairy products and eggs; vegans need fortified foods or supplements. Breastfeeding by vegan mothers can place an infant at risk for vitamin B_{12} deficiency.
- **Fatty acids:** Vegetarians and vegans may be at risk for low levels of eicosapentaenoic acid (EPA) and DHA. The inclusion of sources of linolenic acid (precursor of EPA and DHA), such as walnuts, soy products, flaxseed, and canola oils, are recommended.
- **Calcium and vitamin D:** Without supplementation, vegan diets are low in calcium and vitamin D putting vegans at risk for impaired bone mineralization (see Chapter 51). *Vitamin D-OH levels should be monitored in vegans and supplemented for levels <30 dL.* Calcium sources include leafy greens (with low oxalate: broccoli, kale, or Chinese cabbage). Calcium and vitamin D are found in almond and soy milk, and fortified orange juice.
- **Zinc:** The bioavailability of zinc in plant sources tends to be low because of the presence of phytates and fiber that inhibit zinc absorption (see Chapter 54). Zinc is found in soy products, legumes, grains, cheese, and nuts.

Organic Foods

Parents may prefer organic foods to feed children secondary to concerns regarding chemical and hormonal treatment of animals and produce. The nutritional differences between organic and conventional foods may not be clinically relevant. Children consuming organic foods have lower or no detectable levels of pesticides in their urine compared to those consuming nonorganic foods. It remains unclear whether such a reduction in exposure to chemicals is clinically significant. Organic foods tend to have higher antioxidant levels and lower levels of cadmium. Similarly, despite concerns of parents, the amount of bovine growth hormone in conventional milk is thought to be neither significant nor biologically active in humans. Additionally, milk consumption from estrogen-treated cows does not result in endocrine disruptions in infants. However other chemicals in the environment, such as bisphenol-A (found in plastics), nitrates, endocrine disruptors, and phthalates, should be avoided. Organic certification of a food also suggests the food source is not from a genetically modified nutrient. Because the cost of these foods is generally higher than the cost of other foods, a prudent approach is to explain to families that the scientific basis for choosing organic foods is limited, but if it is their preference and they can afford the added cost, there is no reason not to eat organic foods.

Nutrition as Part of Complementary and Alternative Medicine, Functional Foods, Dietary Supplements, Vitamin Supplements, and Botanical and Herbal Products

The use of nutrition or nutritional supplements as complementary or alternative medicine is increasing, despite limited data on safety and efficacy, especially in children. Many parents assume that if a food or supplement is natural or organic, then there is no potential for risk and some that supplements are beneficial. However, adverse effects of some dietary supplements have been documented. It is difficult for pediatricians to compete against the aggressive marketing through multi-media sources of food supplements to families of healthy and chronically ill children. Additionally, pediatricians must compete against the word-of-mouth and advice from people without a scientific background and those with significant conflicts of interest. One reason to recommend caution to parents when it comes to dietary supplements, including botanical and herbal products, is that in the United States, unlike medications, these products are not evaluated for safety and efficacy before marketing and do not undergo the same level of quality control as medications. The potential for adverse effects or simply for inefficacy is therefore high (see Chapter 64).

Pediatricians are often asked by parents if their children need to receive a daily multivitamin. Unless the child follows a particular diet that may be poor in one or more nutrients for health, cultural, or religious reasons, or if the child has a chronic health condition that puts the child at risk for deficiency in 1 or more nutrients, multivitamins are not indicated. A diet that follows the guidelines of MyPlate contains sufficient nutrients to support healthy growth. Many children do not follow all the guidelines of MyPlate, and parents and pediatricians may be tempted to use multivitamin supplements just to make sure that nutrient deficiencies are avoided. Use of a daily multivitamin supplement can result in a false impression that the child's diet is complete and in decreased efforts to meet dietary recommendations with food rather than the intake of supplements (see Chapter 44) The average U.S. diet provides more than a sufficient amount of most nutrients, including most vitamins. Therefore, multivitamins should not be routinely recommended.

The Institute of Medicine recommends 600 IU of vitamin D per day in all children who drink less than 1,000 mL/day of vitamin D–fortified milk, representing the majority of U.S. children and adolescents. In some specific populations of children at risk for deficiency, supplements of vitamin B_{12}, iron, fat-soluble vitamins, or zinc may be considered.

Food Safety

Constantly keeping food safety issues in mind is an important aspect of feeding infants, children, and adolescents. In addition to choking hazards and food allergies, pediatricians and parents should be aware of food safety issues related to infectious agents and environmental contaminants. Food poisoning with bacteria, viruses, or their toxins are most common with raw or undercooked food, such as oysters, beef, and eggs, or cooked foods that have not been handled or stored properly. The specific bacteria and viruses involved in food poisoning are described in Chapter 340. Many chemical contaminants, such as heavy metals, pesticides, and organic compounds, are present in various foods, usually in small amounts. Because of concerns regarding their child's neurologic development and cancer risk, many questions arise from parents, especially after media coverage of isolated incidents. A recurring debate is the balance between the benefits of seafood for the growing brain and cardiovascular health and the risk of mercury contamination from consuming large predatory fish species. Pediatricians need to become familiar with reliable sources of information, such as the websites of the U.S. Environmental Protection Agency, the FDA, or the CDC. The Food Safety Modernization Act provides the FDA with authority to have stricter control over food production and distribution. The FDA can require that manufacturers develop food safety plans. A good source of information for patients and parents can be found at www.foodsafety.gov.

Nutritional Programming

Emerging epidemiologic evidence suggests that early nutrition starting during fetal development can have long-term impact on growth, and adult health. It is well established that undernutrition in early life can exert a long-term impact in terms of reduced adult height and academic achievements; other data, however, suggest that intrauterine growth restriction is associated with obesity and other adult cardiovascular risk factors. Rapid weight gain in infancy, either following intrauterine growth restriction or a period of malnutrition, is associated

with an increased risk for later obesity. The process that explains these changes has been termed "programming."

Preventive Nutrition Counseling in Pediatric Primary Care

An important part of the primary care well-child visit focuses on nutrition and growth because most families turn to pediatricians for guidance on child nutrition. Preventive nutrition is one of the cornerstones of preventive pediatrics and a critical aspect of anticipatory guidance. The first steps of nutrition counseling are nutritional status assessments, primarily done through growth monitoring and dietary intake assessment. Although dietary assessment is somewhat simple in infants who have a relatively monotonous diet, it is more challenging at older ages. The goals of dietary assessment in the primary care setting need to remain modest and include an idea of the eating patterns (time, location, and environment) and usual diet by asking the parent to describe the child's dietary intake on a typical day or in the last 24 hr. Pediatricians should encourage regularly scheduled meals and 1 or 2 snacks. Alternatively, a basic assessment of the child's consumption of vegetables, fruits, whole grains, low or nonfat dairy products, 100% fruit juice and sugar-sweetened beverages should be assessed. For more ambitious goals of dietary assessment, referral to a registered dietician with pediatric experience is recommended.

Once some understanding of the child's usual diet has been acquired, existing or anticipated nutritional problems should be addressed, such as diet quality, dietary habits, or portion size. For a few nutritional problems, a lack of knowledge can be addressed with nutrition education, but most pediatric preventive nutritional issues, such as overeating or poor food choices, are not the result of lack of parents' knowledge. Therefore, nutrition education alone is insufficient in these situations, and pediatricians need to acquire training in behavior-modification techniques or refer to specialists to assist their patients in engaging in healthy feeding and eating behaviors. The physical, cultural, and family environments in which the child lives should be kept in mind at all times, so that nutrition counseling is relevant and changes are feasible.

One important aspect of nutrition counseling is providing families with sources of additional information and behavioral change tools. Although some handouts are available from government agencies, the AAP, and other professional organizations for families without Internet access, an increasing number of families rely on the Internet to find nutrition information. Therefore, pediatricians need to become familiar with commonly used websites so that they can point families to reliable and unbiased sources of information. Perhaps the most useful websites for reliable and unbiased nutrition information for children are the USDA MyPlate website, the sites of the CDC, FDA, National Institutes of Health, and Institute of Medicine Food and Nutrition Board for government sources and the AAP, American Heart Association, and the Academy of Nutrition and Dietetics (formerly the American Dietetic Association) for professional organization resources. Pediatricians should also be aware of sites that provide biased or even dangerous information, so that they can warn families accordingly. Examples include dieting sites, sites that openly promote dietary supplements or other food products, and the sites of "nonprofit" organizations that are mainly sponsored by food companies or that have other social or political agendas.

Food Assistance Programs in the USA

Several programs exist in the United States to ensure sufficient and high-quality nutrition for children of families who cannot always afford optimal nutrition. One of the most popular federal programs is the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC). This program provides nutrition supplements to a large proportion of pregnant women, postpartum women, and children up to their 5th birthday. One of its strengths is that in order to qualify, families need to regularly visit a WIC nutritionist, who can be a useful resource for nutritional counseling. Other popular programs include school lunches, breakfasts, and after-school meals, as well as daycare and summer nutrition programs. Lower-income families are also eligible for the Supplemental Nutrition Assistance Program, formerly known as the Food Stamp Program. This program provides funds directly to families to purchase various food items in regular food stores.

Chapter 46

Nutrition, Food Security, and Health

Ann Ashworth

MALNUTRITION AS THE INTERSECTION OF FOOD INSECURITY AND HEALTH INSECURITY

Undernutrition is usually an outcome of 3 factors, often in combination: household food supply, child-caring practices, and access to health and water/sanitation services. In famine and emergency settings, food shortage is the foremost factor, but in many countries with widespread undernutrition, food production or access to food might not be the most limiting factor. More important causes might be repeated childhood infections, especially diarrheal diseases linked with an unsafe environment and lack of exclusive breastfeeding, or inadequate complementary feeding practices, or the lack of time families have available for appropriate infant or maternal care. Figure 46-1 shows some of the many causal factors on the pathway to undernutrition and how they extend from household and community levels to national/international levels. Inequitable distribution of resources because of political, economic, and agricultural policies often denies families their right to adequate land, water, food, healthcare, education, and a safe environment, all of which can influence nutritional status.

Families with few economic resources who know how to care for their children and are enabled to do so can often use available food and health services to produce well-nourished children. If food resources and health services are not available in a community, or not utilized, or not accessible to some families, children might become undernourished. Undernutrition is not confined to low-income countries. It has been noted in chronically ill patients in neonatal and pediatric intensive care units in high-income countries and among patients with burns, HIV, tuberculosis, cystic fibrosis, chronic diarrhea syndromes, malignancies, bone marrow transplantation, and inborn errors of metabolism. Severe malnutrition has been reported in affluent communities in infants whose families believe in fad diets, and in infants with food allergies fed nutritionally inadequate foods such as rice "milk," which has a very low protein and micronutrient content (Fig. 46-2).

FOOD SECURITY

Food security exists "when all people, at all times, have access to sufficient, safe, nutritious food to maintain a healthy and active life." Four main dimensions of food security can be identified: **availability**, **access**, **utilization,** and **stability**. *Availability* refers to the supply of food (reflecting the level of food production, food stocks, and net trade). *Access* is at the household level, reflecting purchasing power, household food production, and food/cash transfers received through social safety net programs. The *utilization* dimension recognizes that even when a household has access to food it is not necessarily shared equitably within a household. *Stability* refers to being food secure at all times: Examples of situations that affect stability are the "lean seasons" before a harvest, natural disasters, political unrest, and rising food prices. To be food secure, all 4 dimensions must be met simultaneously.

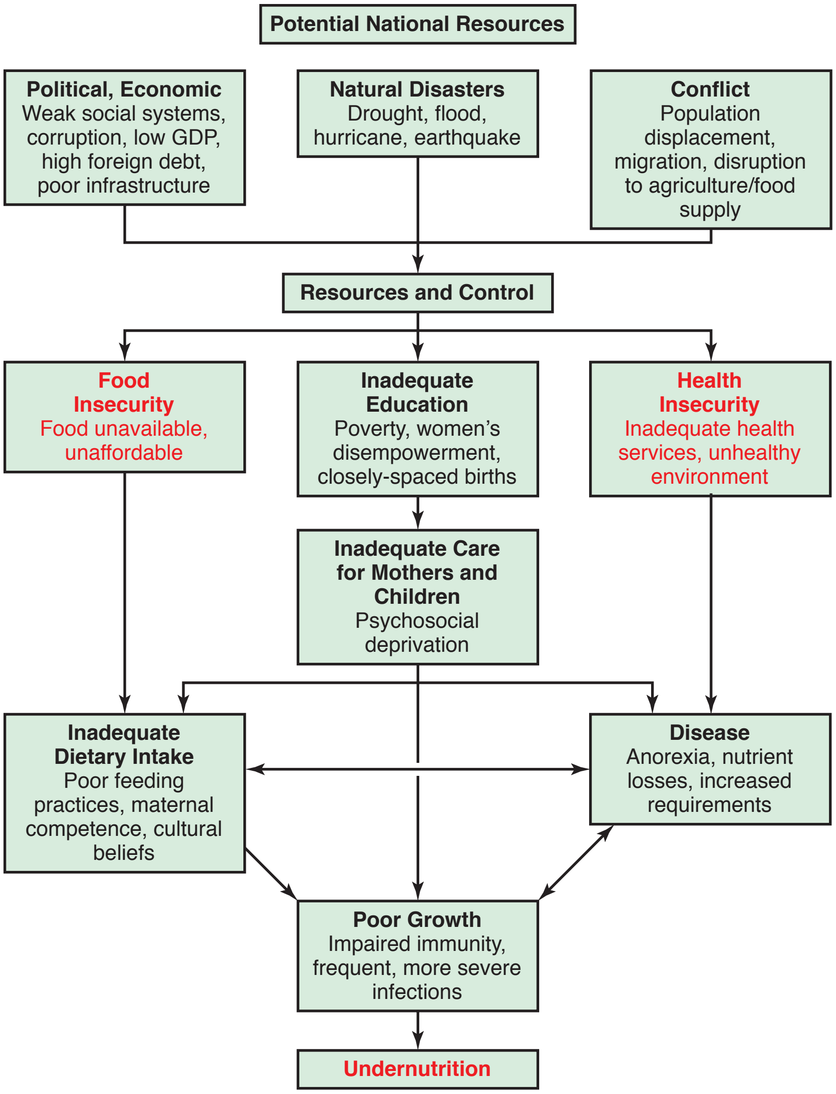

Figure 46-1 Basic, underlying, and immediate causes of undernutrition.

Measuring Food Insecurity

The most commonly used measurement of food insecurity is "undernourishment" (chronic hunger), and is the proportion of the population who are unable to meet daily energy requirements for light activities. It is an estimate calculated by the Food and Agriculture Organization (FAO) based on country-level Food Balance Sheets. It does not take nutrient adequacy into account, but has the advantage of being available for almost all countries annually (although with a time-lag) and assists in monitoring global trends. In addition, FAO measures food access by asking individuals about their experiences over the last 12 mo, such as whether they ran out of food, or skipped meals. The responses are graded from mild to severe food insecurity.

In 2011-2013, FAO estimated that about 842 million people, or 12% of the world's population, were undernourished, 98% of whom were in developing countries. The majority are rural poor subsisting on small plots of land or hired as laborers, and urban poor who lack the means to grow or buy food. Alongside the 0.84 billion people who are underfed, there are 1.5 billion who are overfed reflecting global inequalities, and the "double burden of malnutrition" in low- and middle-income countries.

Nutrition, Food Security, and Poverty

Household food security tracks income closely. With rising incomes, very poor households first increase their dietary energy intake to avert hunger. If incomes rise further there is a shift to more expensive staple foods and then to a more varied diet with a greater proportion of energy from animal sources, fruits and vegetables, fats and sugars, and less from cereals, roots and tubers. National economic growth tends to be accompanied by reductions in stunting, but economic growth can pass by the poor if they work in unaffected sectors, or are unable to take advantage of new opportunities because of lack of education, access to credit, or transportation, or if governments do not channel resources accruing from economic growth to healthcare, education, social protection, and other public services and infrastructure. There is good evidence that economic growth reduces poverty, but does not necessarily reduce undernutrition.

Food Security and Nutrition Targets

World leaders collectively agreed to 8 Millennium Development Goals (MDGs) in 2000. MDG 1 aimed to eradicate extreme poverty and hunger. The target to halve the proportion of people whose income is less than $1 per day was reached at the global level 5 yr ahead of the 2015 target. This was greatly helped by the progress made by China and India. Sub-Saharan Africa is unlikely to reach the target. The reductions in hunger are broadly consistent with those of poverty reduction, and rates of undernourishment in developing regions fell from 23.2% in 1990 to 14.3% in 2011-2013. Sub-Saharan Africa is the region least likely to achieve the target of halving undernourishment by 2015. The prevalence of underweight children (another MDG indicator of "hunger") fell from 29% in 1990 to 17% in 2012 for the

Figure 46-2 A 14 mo old girl with a "flaky paint" dermatitis. *(From Katz KA, Mahlberg MH, Honig PJ, et al: Rice nightmare: kwashiorkor in 2 Philadelphia-area infants fed Rice Dream beverage,* J Am Acad Dermatol *52(5 Suppl 1):S69–S72, 2005.)*

developing regions combined, but the rate of decline is thought insufficient to reach the global target by 2015. Rural children are almost twice as likely to be underweight as urban children, and the poorest quintile is almost 3 times as likely to be underweight as the richest quintile.

Sustainable Development Goals are expected to follow on from the MDGs. In addition, in 2012 the World Health Assembly agreed to 6 global nutrition targets to be reached by 2025, measured against a 2010 baseline, and the United Nations Secretary-General launched the Zero Hunger Challenge with 5 objectives that "would boost economic growth, reduce poverty and safeguard the environment" and "would foster peace and stability" (Table 46-1).

Table 46-1 Global Food Security and Nutrition Targets

ZERO HUNGER CHALLENGE OBJECTIVES	WORLD HEALTH ASSEMBLY GLOBAL NUTRITION TARGETS FOR 2025
• Access to an adequate and stable food supply for all • Elimination of stunting in children <2 yr and no malnutrition in pregnancy and early childhood • Sustainable food systems • Doubling of smallholder productivity and income, particularly for women • No loss or waste of food, and responsible consumption	• A 40% reduction in the number of stunted children <5 yr • A 50% reduction in anemia in women of reproductive age • A 30% reduction in low birthweight • No increase in childhood overweightness • Increase exclusive breastfeeding rates to at least 50% in the first 6 months • Reduce and maintain childhood wasting to less than 5%

Future Food Security

Between now and 2050 the world's population is expected to rise to around 9 billion, and an increase in food supply of 70-100% will be needed to feed this larger, more urban, and more affluent populace. Over this same period, the world's food supply is expected to diminish unless action is taken. Accelerating the decline in fertility rates and reducing overconsumption are basic, but difficult, actions to bridge the gap between increasing demand and diminishing supply. Equally challenging actions include limiting climate disruption, increasing the efficiency of food production, reducing waste, and reducing the demand for meat and dairy foods.

- *Limit climate disruption:* Drought, floods, and other extreme weather events are becoming more prevalent and destroy crops and livestock, often on a huge scale. Rising sea levels will lead to loss of productive land through inundation and salinization. Acidification of oceans will reduce marine harvests. Curbing greenhouse gas emissions is essential to minimize climate disruption, hence the aim to (a) cut fossil fuel use by at least half of present levels by 2050 so as to reduce CO_2 emissions and (b) change livestock husbandry and agronomic practices to reduce methane and nitrous oxide emissions.
- *Increase efficiency of food production*: Expanding the area of agricultural land to any large extent (e.g., by deforestation) is not a sustainable option because of adverse consequences on ecosystems and biodiversity, although some expansion of food production could be achieved by switching good quality land away from first-generation biofuels. For example, 40% of the U.S. corn harvest in 2010 went to biofuels. Efforts to increase the intensity of production need to be environmentally sustainable. These include optimizing yields by soil and water conservation, removal of technical and financial constraints faced by farmers, and breeding resource-efficient crops and livestock that are also climate-resilient and pest/disease-resistant.
- *Reduce waste*: Some 30-40% of food is wasted, either between harvesting and the market, or during retail, at home, and in the food service industry. Better transport and storage facilities in developing countries, less stringent sell-by dates, lower cosmetic standards for fruits and vegetables, and ending supersized portions would help reduce waste.
- *Change diets:* As wealth increases, so does the demand for processed foods, meat, dairy products, and fish. About one-third of global cereal production is fed to animals, so reducing consumption of meat from grain-fed livestock and increasing the proportion derived from the most efficient sources (pigs and poultry) would allow more people to be fed from the same amount of land.

UNDERNUTRITION

The greatest risk of undernutrition (underweight, stunting, wasting, and micronutrient deficiencies) occurs in the first 1000 days, from conception to 24 mo of age, and this early damage to growth and development can have adverse consequences in later life on health, intellectual ability, school achievement, work productivity, and earnings. Governments and agencies are therefore advised to focus interventions on this critical window of opportunity. For folate deficiency, which increases the risk of birth defects, this particular window of opportunity is before conception.

Measurement of Undernutrition

The term ***malnutrition*** encompasses both ends of the nutrition spectrum, from undernutrition to overweight. Many poor nutritional outcomes begin *in utero* and are manifest as low birthweight (LBW, <2,500 g). Preterm delivery and fetal growth restriction are the 2 main

Table 46-2 Classification of Undernutrition

CLASSIFICATION	INDEX	GRADING
Gomez (underweight)	90-75% of median weight-for-age	Grade 1 (mild)
	75-60%	Grade 2 (moderate)
	<60%	Grade 3 (severe)
Waterlow (wasting)	90-80% of median weight-for-height	Mild
	<70%	Severe
Waterlow (stunting)	95-90% of median height-for-age	Mild
	90-85%	Moderate
	<85%	Severe
WHO (wasting)	<–2 to >–3 SD weight-for-height	Moderate
	<–3	Severe
WHO (stunting)	<–2 to >–3 SD height-for-age	Moderate
	<–3	Severe
WHO (wasting) (for age group 6-59 mo)	115-125 mm mid-upper arm circumference	Moderate
	<115 mm	Severe

Figure 46-3 Measuring mid-upper arm circumference. *(Image courtesy of Nyani Quarmyne/Panos Pictures.)*

causes of LBW, with prematurity relatively more common in richer countries and fetal growth restriction relatively more common in poorer countries.

Nutritional status is often assessed in terms of anthropometry (Table 46-2). International standards of normal child growth under optimum conditions from birth to 5 yr have been established by the World Health Organization (WHO). To compile the standards, longitudinal data from birth to 24 mo of healthy, breastfed, term infants were combined with cross-sectional measurements of children ages 18-71 mo. The standards allow normalization of anthropometric measures in terms of z scores (standard deviation scores). A z-score is the child's height (weight) minus the median height (weight) for the age and sex of the child divided by the relevant standard deviation. The standards are applicable to all children everywhere, having been derived from a large multicountry study reflecting diverse ethnic backgrounds and cultural settings.

Height-for-age (or length-for-age for children <2 yr) is a measure of linear growth, and a deficit represents the cumulative impact of adverse events, usually in the first 1,000 days from conception, that result in *stunting,* or chronic malnutrition. A low height-for-age typically reflects socioeconomic disadvantage. A low **weight-for-height**, or *wasting*, usually indicates acute malnutrition. Conversely, a high weight-for-height indicates *overweight*. **Weight-for-age** is the most commonly used index of nutritional status, although a low value has limited clinical significance as it does not differentiate between wasting and stunting. Weight-for-age has the advantage of being somewhat easier to measure than indices that require height measurements. In humanitarian emergencies and some field settings, **mid-upper arm circumference** is used for screening wasted children (Fig. 46-3).

Body mass index (BMI) is calculated by dividing weight in kilograms by the square of height in meters. For children, BMI is age- and gender-specific. BMI-for-age can be used from birth to 20 yr and is a screening tool for thinness (<–2 SD), overweight (between +1 SD and +2 SD), and obesity (>+2 SD). To diagnose obesity, additional measures of adiposity are desirable as a high BMI can result from high muscularity, and not only from excess subcutaneous fat.

Micronutrient deficiencies are another dimension of undernutrition. Those of particular public health significance are vitamin A, iodine, iron, and zinc.

Vitamin A deficiency is caused by a low intake of retinol (in animal foods) or its carotenoid precursors, mainly beta-carotene (in orange-colored fruits and vegetables and dark green leaves) (see Chapter 48). The prevalence of clinical deficiency is assessed from symptoms and signs of xerophthalmia (principally night blindness and Bitot spots). Subclinical deficiency is defined as serum retinol concentration <0.70 µmol/L. Vitamin A deficiency is the leading cause of preventable blindness in children. It is also associated with a higher morbidity and mortality among young children.

Iodine deficiency is the main cause of preventable mental impairment (see Chapter 54). An enlarged thyroid (goiter) is a sign of deficiency. Severe deficiency in pregnancy causes fetal loss and permanent damage to the brain and central nervous system in surviving offspring (cretinism). It can be prevented by iodine supplementation before conception or during the first trimester of pregnancy. Postnatal iodine deficiency is associated with impaired mental function and growth retardation. The median urinary iodine concentration in children ages 6-12 yr is used to assess the prevalence of deficiency in the general population, and a median of <100 µg/L indicates insufficient iodine intake.

Iron-deficiency anemia is common in childhood either from low iron intakes or poor absorption, or as a result of illness or parasite infestation (see Chapter 54). Women also have relatively high rates of anemia as a result of menstrual blood loss, pregnancy, low iron intakes, poor absorption, and illness. Hemoglobin cutoffs to define anemia are 110 g/L for children 6-59 mo, 115 g/L for children 5-11 yr, and 120 g/L for children 12-14 yr. Cutoffs to define anemia for nonpregnant women are 120 g/L, 110 g/L for pregnant women, and 130 g/L for men.

Zinc deficiency increases the risk of morbidity and mortality from diarrhea, pneumonia, and possibly other infectious diseases (see Chapter 54). Zinc deficiency also has an adverse effect on linear growth. Deficiency at the population level is assessed from dietary zinc intakes.

Prevalence of Undernutrition

It is estimated that approximately 15% of births in low- and middle-income countries in 2010 were LBW. Rates of LBW are highest (26%) in southern Asia, and are twice those of sub-Saharan Africa. India accounts for approximately 40% of the world's low-weight births. Globally, in 2011 16% of children <5 yr of age were *underweight* (weight-for-age <–2 SD). The global prevalence of *stunting* (height-for-age <–2 SD) has declined from an estimated 40% to 26% over the last 20 yr, with the greatest reductions having taken place in Asia. Stunting prevalence is now highest in the African region (36% prevalence). *Wasting* (weight-for-height <–2 SD) affects 8% of children <5 yr, the prevalence having changed little over the past 2 decades. These figures represent 101 million underweight children, 165 million stunted children, and 52 million wasted children.

Asia carries 69% of the global burden of underweight children, 58% of the global burden of stunted children, and 70% of the global burden

of wasted children because of the combination of large population size and high prevalence. Africa carries most of the remaining global burden. For children <5 yr, the global prevalence is estimated to be 33% for *vitamin A deficiency*, 29% for *iodine deficiency*, 17% for *zinc deficiency*, and 18% for *iron-deficiency anemia*. Prevalence of micronutrient deficiencies tends to be highest in Africa. For pregnant women, the estimated prevalence of vitamin A deficiency is 15% and for iron-deficiency anemia 19%.

Rates of clinical deficiency of vitamin A in children <5 yr have been declining, probably as a result of high-dose vitamin A supplementation programs and measles vaccination (as measles leads to sizeable urinary loss of vitamin A), but subclinical deficiency remains widespread (more than 90 million children). Large-scale availability of iodized salt has reduced rates of iodine deficiency substantially, and iodized salt now reaches an estimated 70% of households. In contrast, progress in reducing rates of iron-deficiency anemia is slow, and rates remain largely static.

Consequences of Undernutrition

The most profound consequence of undernutrition is premature death (Table 46-3). Fetal growth restriction together with suboptimal breastfeeding in the first month of life contribute to 19% of all deaths in children <5 yr (1.3 million deaths/yr). When the effects of stunting, wasting and deficiencies of vitamin A and zinc are also considered, these 6 items jointly contribute to 45% of global child deaths (3.1 million deaths/yr), and many more are disabled or stunted for life. Anemia contributes to over one-quarter of maternal deaths.

The risk of child death from infectious diseases increases even with mild undernutrition, and as the severity of undernutrition increases, the risk increases exponentially (Table 46-4). Undernutrition impairs immune function and other host defenses, consequently childhood infections are more severe and longer lasting in undernourished children and more likely to be fatal compared with the same illnesses in well-nourished children. Also, infections can adversely affect nutritional status, and young children can quickly enter a cycle of repeated infections and ever-worsening malnutrition. Even for the survivors, physical and cognitive damage as a result of undernutrition can impact their future health and economic well-being. For girls, the cycle of undernutrition is passed on to the next generation when undernourished women give birth to LBW babies.

Fetal growth restriction and early childhood undernutrition also have consequences for adult chronic illness. LBW is associated with an increased risk of hypertension, stroke, and type 2 diabetes in adults. The increased risk is thought to reflect "fetal programming," a process by which fetal undernutrition leads to permanent changes in the structure and metabolism of organs and systems that manifest as disease in later life. The risk is exacerbated by low weight gain during the first 2 yr of life. The increased risk of adult chronic disease emanating from undernutrition in early life is a particular challenge to low-income countries with rapid economic growth.

Stunting before the age of 3 yr is associated with poorer motor and cognitive development and altered behavior in later years. The effect is

Table 46-3 Global Deaths in Children <5 yr Attributed to Nutritional Conditions

CONDITION	ATTRIBUTABLE DEATHS	% OF TOTAL DEATHS <5 YR
(a) Fetal growth restriction (<1 mo)	817,000	11.8
(b) Stunting (1-59 mo)	1,017,000	14.7
(c) Wasting (1-59 mo)	875,000	12.6
(d) Zinc deficiency (12-59 mo)	116,000	1.7
(e) Vitamin A deficiency (6-59 mo)	157,000	2.3
(f) Suboptimal breastfeeding (0-23 mo)	804,000	11.6
Joint effects of (a) + (f)	1,348,000	19.4

6-13 DQ (developmental quotient) points. Iodine and iron deficiencies also lead to loss of cognitive potential. Indications are that children living in areas of chronic iodine deficiency have an average reduction in IQ of 12-13.5 points compared with children in iodine-sufficient areas. Iron deficiency has a detrimental effect on the motor development of children <4 yr and on cognition of school-age children. The estimated deficit is 1.73 IQ points for each 10 g/L decrease in hemoglobin concentration.

Undernutrition can have substantial economic consequences for survivors and their families. The consequences can be quantified in 5 categories: increased costs of healthcare, either neonatal care for LBW babies or treatment of illness for infants and young children; productivity losses (and hence reduced earnings) associated with smaller stature and muscle mass; productivity losses from reduced cognitive ability and poorer school performance; increased costs of chronic diseases associated with fetal and early child malnutrition; and consequences of maternal undernutrition on future generations. The impact of nutrition on earnings appears to be independent of the effects of childhood deprivation.

Key Interventions

Interventions to address child undernutrition can be divided into those that address immediate causes (*nutrition-specific interventions*) and those that address underlying causes (*nutrition-sensitive interventions*) (Table 46-5). In the short-term, nutrition-specific interventions (e.g., salt iodization) can have substantial impacts even in the absence of economic growth, and micronutrient interventions (supplementation and fortification) are consistently ranked by economists of the Copenhagen Consensus Center as the most cost-effective investment. Increased attention is being given to nutrition-sensitive interventions as the best means of sustainably eliminating malnutrition, and to multisectoral policies that harness the synergism between the 2 types of intervention. Cross-sectoral linkages between agriculture, nutrition, and health are 1 example.

To reduce the adverse consequences of undernutrition on mortality, morbidity, and cognitive development, interventions must encompass both fetal and postnatal periods. Preventing LBW is essential, with emphasis on prevention of low maternal BMI and anemia, and in the longer term, prevention of low maternal stature. Other measures include smoking cessation, birth spacing, delaying pregnancy until after 18 yr of age, and intermittent preventive treatment of malaria. In the postnatal period, promotion and support of exclusive breastfeeding is a high priority. Although the Baby Friendly Hospital Initiative has a marked benefit on rates of exclusive breastfeeding in hospital, postnatal counseling from community workers or volunteers is needed to facilitate continuation of exclusive breastfeeding at home for 6 mo. Most studies show a lower risk of HIV transmission with exclusive breastfeeding than with mixed breastfeeding. The risk of transmission of HIV by breastfeeding is approximately 5-20% depending on duration, but can be reduced to <2% with antiretroviral drugs. Even without antiretroviral drugs, exclusively breastfed children of HIV-infected mothers in low-income countries have lower mortality than non-breastfed children, as the latter are at increased risk of death from diarrhea and pneumonia.

Interventions to improve infant feeding must be designed for the local setting and thus require careful formative research during their development. Messages should be few in number, feasible, and culturally appropriate. For complementary feeding, nutrient-rich, energy-dense mixtures of foods, and responsive feeding, are often emphasized. Where adequate complementary feeding is difficult to achieve and subclinical deficiencies are common, high-dose vitamin A supplementation every 6 mo in children <5 yr of age can reduce child mortality by 5-15% and zinc supplementation can reduce 1-4 yr mortality by 18%, diarrhea incidence by 13%, and pneumonia incidence by 19%. Monitoring of child growth provides an early alert to a nutrition or health problem but is only worthwhile if accompanied by good counseling and growth promotion activities. The impact of growth monitoring and promotion will be related to coverage, intensity of contact, health worker performance and communications skills, adequacy of resources, and the motivation and ability of families to follow agreed actions.

Table 46-5 Examples of Nutrition-Specific and Nutrition-Sensitive Interventions

NUTRITION-SPECIFIC INTERVENTIONS	NUTRITION-SENSITIVE INTERVENTIONS
• Promotion and support for exclusive breastfeeding for 6 mo, and continued breastfeeding for at least 2 yr • Promotion of adequate, timely, and safe complementary feeding from 6 mo • Increased micronutrient intake through dietary diversity • Micronutrient supplements for pregnant women (iron/folate) and young children (vitamin A, iron, zinc) in deficient areas • Zinc supplements to children during and after diarrhea (10-20 mg/day for 2 wk) • Prevention and treatment of severe acute malnutrition • Crop biofortification, food fortification, salt iodization • Reduced heavy physical activity in pregnancy	• Increased access to affordable, nutritious food; smallholder agriculture; credit and microfinance • Postharvest food processing and preservation • Vaccination against neonatal and childhood illness; access to healthcare • Improved water/sanitation and hygiene (e.g., handwashing with soap) • Education; women's empowerment; gender equality • Social protection (e.g., cash transfers) • Malaria prevention (vector control/bednets); intermittent preventive treatment during pregnancy and in children 3-59 mo • Birth spacing; delaying pregnancy until after 18 yr of age

Clinical Manifestations and Treatment of Undernutrition

Treatment of vitamin and mineral deficiencies is discussed in Chapters 48-54. Treatment of low birthweight and intrauterine growth restriction are discussed respectively in Chapter 97.

SEVERE ACUTE MALNUTRITION

Severe acute malnutrition is defined as severe wasting and/or bilateral edema.

Severe wasting is extreme thinness diagnosed by a weight-for-length (or height) below −3 SD of the WHO Child Growth Standards. In children ages 6-59 mo, a mid-upper arm circumference <115 mm also denotes extreme thinness: a color-banded tape (see Fig. 46-3) is a convenient way of screening children in need of treatment.

Bilateral edema is diagnosed by grasping both feet, placing a thumb on top of each, and pressing gently but firmly for 10 seconds. A pit (dent) remaining under each thumb indicates bilateral edema.

This definition of severe acute malnutrition distinguishes wasted/edematous children from those who are stunted, as the latter (although underweight) are not a priority for acute clinical care as their deficits in height and weight cannot be corrected in the short term. The previous name *protein-energy malnutrition* is avoided, as it oversimplifies the complex multideficiency etiology. Other terms are *marasmus* (severe wasting), *kwashiorkor* (characterized by edema), and *marasmic-kwashiorkor* (severe wasting + edema).

Children with severe acute malnutrition have had a diet insufficient in energy and nutrients relative to their needs. The magnitude of the deficits will differ depending on the duration of inadequacy, quantity and diversity of food consumed, presence of antinutrients (such as phytate), individual variation in requirements, and number and severity of coexisting infections and their duration. Infections can lead to profound nutrient deficits and imbalances: For example, amino acids are diverted to form acute-phase proteins and there are losses through diarrhea of potassium, magnesium, vitamin A, and zinc, and of glycine and taurine linked to small bowel bacterial overgrowth. Deficits can

also arise from increased nutrient utilization in response to noxae (e.g., cysteine and methionine to detoxify dietary cyanogens). Heterogeneity in the extent and nature of the deficits and imbalances, reflecting the diverse pathways to severe acute malnutrition, helps explain why affected children differ in their clinical presentation and degree of metabolic disturbance. Children who develop edematous malnutrition are more likely than nonedematous children to have been exposed to noxae that generate oxidative stress and/or to have greater deficits in free radical-scavenging antioxidants (glutathione, vitamins A, C, and E, and essential fatty acids) or cofactors (zinc, copper, selenium).

Clinical Manifestations of Severe Acute Malnutrition (Table 46-6)

Severe wasting (Fig. 46-4) is most visible on the thighs, buttocks, and upper arms, and over the ribs and scapulae where loss of fat and skeletal muscle is greatest. Wasting is preceded by failure to gain weight and then by weight loss. The skin loses turgor and becomes loose as subcutaneous tissues are broken down to provide energy. The face may retain a relatively normal appearance, but eventually becomes wasted and wizened. The eyes may be sunken from loss of retroorbital fat, and lachrymal and salivary glands may atrophy leading to lack of tears and a dry mouth. Weakened abdominal muscles and gas from bacterial overgrowth of the upper gut may lead to a distended abdomen. Severely wasted children are often fretful and irritable.

In *edematous malnutrition*, the edema is most likely to appear first in the feet and then in the lower legs. It can quickly develop into generalized edema affecting also the hands, arms, and face (Fig. 46-5). Skin changes commonly occur over the swollen limbs and include dark, crackled peeling patches (flaky paint dermatosis) with pale skin underneath that is easily infected. The hair is sparse and easily pulled out and may lose its curl. In dark-haired children, the hair may turn pale or reddish. The liver is often enlarged with fat. Children with edema are miserable and apathetic, and often refuse to eat.

Table 46-6 Clinical Signs of Malnutrition

SITE	SIGNS
Face	Moon face (kwashiorkor), simian facies (marasmus)
Eye	Dry eyes, pale conjunctiva, Bitot spots (vitamin A), periorbital edema
Mouth	Angular stomatitis, cheilitis, glossitis, spongy bleeding gums (vitamin C), parotid enlargement
Teeth	Enamel mottling, delayed eruption
Hair	Dull, sparse, brittle hair, hypopigmentation, flag sign (alternating bands of light and normal color), broomstick eyelashes, alopecia
Skin	Loose and wrinkled (marasmus), shiny and edematous (kwashiorkor), dry, follicular hyperkeratosis, patchy hyper- and hypopigmentation (crazy paving or flaky paint dermatoses), erosions, poor wound healing
Nails	Koilonychia, thin and soft nail plates, fissures, or ridges
Musculature	Muscle wasting, particularly buttocks and thighs; Chvostek or Trousseau sign (hypocalcemia)
Skeletal	Deformities, usually as a result of calcium, vitamin D, or vitamin C deficiencies
Abdomen	Distended: hepatomegaly with fatty liver; ascites may be present
Cardiovascular	Bradycardia, hypotension, reduced cardiac output, small vessel vasculopathy
Neurologic	Global developmental delay, loss of knee and ankle reflexes, impaired memory
Hematologic	Pallor, petechiae, bleeding diathesis
Behavior	Lethargic, apathetic, irritable on handling

From Grover Z, Ee LC: Protein energy malnutrition, Pediatr Clin N Am *56:1055–1068, 2009.*

Pathophysiology

When a child's intake is insufficient to meet daily needs, physiologic and metabolic changes take place in an orderly progression to conserve energy and prolong life. This process is called *reductive adaptation*. Fat stores are mobilized to provide energy. Later protein in muscle, skin, and the gastrointestinal tract is mobilized. Energy is conserved by reducing physical activity and growth, reducing basal metabolism and the functional reserve of organs and by reducing inflammatory and immune responses. These changes have important consequences:

- The liver makes glucose less readily, making the child more prone to hypoglycemia. It produces less albumin, transferrin, and other transport proteins. It is less able to cope with excess dietary protein and to excrete toxins.
- Heat production is less, making the child more vulnerable to hypothermia.
- The kidneys are less able to excrete excess fluid and sodium, and fluid easily accumulates in the circulation, increasing the risk of fluid overload.
- The heart is smaller and weaker and has a reduced output, and fluid overload readily leads to death from cardiac failure.
- Sodium builds up inside cells due to leaky cell membranes and reduced activity of the sodium/potassium pump, leading to excess body sodium, fluid retention, and edema.
- Potassium leaks out of cells and is excreted in urine, contributing to electrolyte imbalance, fluid retention, edema, and anorexia.
- Loss of muscle protein is accompanied by loss of potassium, magnesium, zinc, and copper.

Figure 46-4 Child with severe wasting.

- The gut produces less gastric acid and enzymes. Motility is reduced, and bacteria may colonize the stomach and small intestine, damaging the mucosa and deconjugating bile salts. Digestion and absorption are impaired.
- Cell replication and repair are reduced, increasing the risk of bacterial translocation through the gut mucosa.
- Immune function is impaired, especially cell-mediated immunity. The usual responses to infection may be absent, even in severe illness, increasing the risk of undiagnosed infection.
- Red cell mass is reduced, releasing iron which requires glucose and amino acids to be converted to ferritin, increasing the risk of hypoglycemia and amino acid imbalances. If conversion to ferritin is incomplete, unbound iron promotes pathogen growth and formation of free radicals.
- Micronutrient deficiencies limit the body's ability to deactivate free radicals, which cause cell damage. Edema and hair/skin changes are outward signs of cell damage.

When prescribing treatment it is essential to take these changes in function into account, otherwise organs and systems will be overwhelmed and death will rapidly ensue.

Figure 46-5 Child with generalized edema.

Principles of Treatment

Figure 46-6 shows the 10 steps of treatment, which are separated into 2 phases referred to as stabilization and rehabilitation. These steps apply to all clinical forms and all geographic locations, including North America and Europe. The aim of the stabilization phase is to repair cellular function, correct fluid and electrolyte imbalance, restore homeostasis, and prevent death from the interlinked triad of hypoglycemia, hypothermia, and infection. The aim of the rehabilitation phase is to restore wasted tissues (i.e., catch-up growth). It is essential that treatment proceeds in an ordered progression and that the metabolic machinery is repaired before any attempt is made to promote weight gain. Pushing ahead too quickly risks inducing the potentially fatal "refeeding syndrome."

Caregivers bring children to health facilities because of illness, rarely because of their malnutrition. A common mistake among healthcare providers is to focus on the illness and treat as for a well-nourished child. This approach ignores the deranged metabolism in malnourished children and can be fatal. Such children should be considered as severely malnourished with a complication, and treatment should follow the 10 steps. Two other potentially fatal mistakes are to treat edema with a diuretic and to give a high-protein diet in the early phase of treatment.

- ***Emergency treatment***: Table 46-7 summarizes the therapeutic directives for malnourished children with shock and other emergency conditions. Note that treatment of shock in these children is different (less rapid, smaller volume, different fluid) from treatment of shock in well-nourished children. This difference is because shock from dehydration and sepsis often coexist and are difficult to differentiate on clinical grounds. Thus one has to be guided by the response to treatment: children with dehydration respond to IV fluid whereas those with septic shock will not respond. Since severely malnourished children can quickly succumb to fluid overload, they must be monitored closely.
- ***Stabilization***: Table 46-8 summarizes the therapeutic directives for stabilization steps 1-7. Giving broad-spectrum antibiotics (Table 46-9) and feeding frequent small amounts of F75 (a specially formulated low-lactose milk with 75 kcal and 0.9 g protein per

Figure 46-6 The 10 steps of treatment for severe acute malnutrition and their approximate time frames.

Table 46-7 Emergency Treatment in Severe Malnutrition

CONDITION	IMMEDIATE ACTION
Shock • lethargic or unconscious and • cold hands Plus either: • slow capillary refill (longer than 3 sec) or • weak fast pulse	1. Give oxygen 2. Give sterile 10% glucose (5 mL/kg) by IV 3. Give IV fluid at 15 mL/kg over 1 hr, using: • Ringers lactate with 5% dextrose or • half-normal saline with 5% dextrose or • half-strength Darrow solution with 5% dextrose • if all of the above are unavailable, Ringer lactate 4. Measure and record pulse and respirations at the start and every 10 minutes If there are signs of improvement (pulse and respiration rates fall) repeat IV 15 mL/kg for 1 more hr. Then switch to oral or nasogastric rehydration with ReSoMal, 5-10 mL/kg in alternate hr (see Table 46-8 step 3) If there are no signs of improvement assume septic shock and: 1. Give maintenance fluid IV (4 mL/kg/hr) while waiting for blood 2. Order 10 mL/kg fresh whole blood and transfuse slowly over 3 hr. If signs of heart failure, give 5-7 mL/kg packed cells rather than whole blood 3. Give furosemide 1 mL/kg IV at the start of the transfusion
Hypoglycemia Blood glucose less than 3 mmol/L	See Table 46-8 step 1 for treatment
Severe dehydration	Do *not* give IV fluids except in shock See Table 46-8 step 3 for treatment
Very severe anemia Hb less than 4 g/dL	If very severe anemia (or Hb 4-6 g/dL AND respiratory distress): 1. Give whole blood 10 mL/kg slowly over 3 hr. If signs of heart failure, give 5-7 mL/kg packed cells rather than whole blood 2. Give furosemide 1 mL/kg IV at the start of the transfusion
Emergency eye care Corneal ulceration	If corneal ulceration: 1. Give vitamin A immediately (age <6 mo 50,000 IU, 6-12 mo 100,000 IU, >12 mo 200,000 IU) 2. Instill 1 drop atropine (1%) into affected eye to relax the eye and prevent the lens from pushing out

Table 46-8 Therapeutic Directives for Stabilization

STEP	PREVENTION	TREATMENT
1. Prevent/treat hypoglycemia blood glucose <3 mmol/L	Avoid long gaps without food and minimize need for glucose: 1. Feed immediately 2. Feed every 3 hr day and night (2 hr if ill) 3. Feed on time 4. Keep warm 5. Treat infections (they compete for glucose) *Note:* Hypoglycemia and hypothermia often coexist, and are signs of severe infection	If conscious: 1. 10% glucose (50 mL), or a feed (see step 7), or 1 teaspoon sugar under the tongue-whichever is quickest 2. Feed every 2 hr for at least the first day. Initially give ¼ of feed every 30 min 3. Keep warm 4. Start broad-spectrum antibiotics If unconscious: 1. Immediately give sterile 10% glucose (5 mL/kg) by IV 2. Feed every 2 hr for at least first day. Initially give ¼ of feed every 30 min. Use nasogastric (NG) tube if unable to drink 3. Keep warm. 4. Start broad-spectrum antibiotics
2. Prevent/treat hypothermia axillary <35°C (95°F); rectal <35.5°C (95.9°F)	Keep warm and dry and feed frequently 1. Avoid exposure 2. Dress warmly, including head and cover with blanket 3. Keep room hot; avoid draughts 4. Change wet clothes and bedding 5. Do not bathe if very ill 6. Feed frequently day and night 7. Treat infections	Actively rewarm 1. Feed 2. Skin-to-skin contact with carer ("kangaroo technique") or dress in warmed clothes, cover head, wrap in warmed blanket and provide indirect heat (e.g. heater; transwarmer mattress; incandescent lamp) 3. Monitor temperature hourly (or every 30 min if using heater) 4. Stop rewarming when rectal temperature is 36.5°C (97.7°F)
3. Prevent/treat dehydration	Replace stool losses 1. Give ReSoMal after each watery stool. ReSoMal (37.5 mmol Na/L) is a low-sodium rehydration solution for malnutrition	Do *not* give IV fluids unless the child is in shock 1. Give ReSoMal 5 mL/kg every 30 min for first 2 hr orally or NG tube 2. Then give 5-10 mL/kg in alternate hours for up to 10 hr. Amount depends on stool loss and eagerness to drink. Feed in the other alternate hour 3. Monitor hourly and stop if signs of overload develop (pulse rate increases by 25 beats/min and respiratory rate by 5 breaths/min; increasing edema; engorged jugular veins) 4. Stop when rehydrated (3 or more signs of hydration: less thirsty, passing urine, skin pinch less slow, eyes less sunken, moist mouth, tears, less lethargic, improved pulse and respiratory rate).

Continued

Table 46-8 Therapeutic Directives for Stabilization—cont'd

STEP	PREVENTION	TREATMENT
4. Correct electrolyte imbalance—deficit of potassium and magnesium, excess sodium		1. Give extra potassium (4 mmol/kg/day) and magnesium (0.6 mmol/kg/day) for at least 2 wk (see Table 46-12) *Note:* Potassium and magnesium are already added in Nutriset F75 and F100 packets
5. Prevent/treat infections	Minimize risk of cross-infection 1. Avoid overcrowding 2. Wash hands 3. Give measles vaccine to unimmunized children age >6 mo	Infections are often silent. Starting on the first day, give broad-spectrum antibiotics to all children. 1. For antibiotic choices/schedule see Table 46-9 2. Ensure all doses are given, and given on time 3. Cover skin lesions so they do not become infected *Note:* Avoid steroids as they depress immune function
6. Correct micronutrient deficiencies	*Note:* Folic acid, multivitamins, zinc, copper, and other trace minerals are already added in Nutriset F75 and F100 packets	Do *not* give iron in the stabilization phase 1. Give vitamin A on day 1 (under 6 mo 50,000 units; 6-12 mo 100,000 units; >12 mo 200,000 units) if child has any eye signs of vitamin A deficiency or has had recent measles. Repeat this dose on days 2 and 14 2. Folic acid 1 mg (5 mg on day 1) 3. Zinc (2 mg/kg/day) and copper (0.3 mg/kg/day).These are in the electrolyte/mineral solution and Combined Mineral Vitamin mix (CMV) and can be added to feeds and ReSoMal 4. Multivitamin syrup or CMV
7. Start cautious feeding		1. Give 8-12 small feeds of F75 to provide 130 mL/kg/day,100 kcal/kg/day and 1-1.5 g protein/kg/day 2. If gross edema, reduce volume to 100 ml/kg/day 3. Keep a 24-hr intake chart. Measure feeds carefully. Record leftovers 4. If child has poor appetite, coax and encourage to finish the feed. If unfinished, reoffer later. Use NG tube if eating 80% or less of the amount offered 5. If breastfed, encourage continued breastfeeding but also give F75 6. Transfer to F100 when appetite returns (usually within 1 wk) and edema has been lost or is reduced 7. Weigh daily and plot weight.

Table 46-9 Recommended Antibiotics*

	GIVE
If no complications	Amoxicillin oral 25 mg/kg twice daily for 5 days
If complications (shock, hypoglycemia, hypothermia, skin lesions, respiratory or urinary tract infections, or lethargy/sickly)	Gentamicin (7.5 mg/kg IV or IM) once daily for 7 days *and* Ampicillin (50 mg/kg IV or IM) every 6 hr for 2 days, then oral amoxicillin (25-40 mg/kg) every 8 hr for 5 days

*Local resistance patterns may require these to be adjusted: Ensure that there is Gram-negative cover.
If specific infections are identified, add appropriate antibiotics.
For persistent diarrhea/small bowel overgrowth, add metronidazole (7.5 mg/kg oral) every 8 hr for 7 days.

100 mL to which potassium, magnesium, and micronutrients are added), will reestablish metabolic control, treat edema, and restore appetite. The parenteral route should be avoided; children who lack appetite should be fed by nasogastric tube, as nutrients delivered within the gut lumen help in its repair. Table 46-10 gives recipes for preparing the special feeds, and their nutrient composition. Two recipes for F75 are shown: one requires no cooking, the other is cereal-based and has a lower osmolality, which may benefit children with persistent diarrhea. F75 is also available commercially in which maltodextrins replace some of the sugar and to which potassium, magnesium, minerals, and vitamins are already added.

Dehydration status is easily misdiagnosed in severely wasted children, as the usual signs (such as slow skin pinch, sunken eyes) may be present even without dehydration. Rehydration must therefore be closely monitored for signs of fluid overload. Serum electrolyte levels can be misleading because of sodium leaking from the blood into cells and potassium leaking out of cells. Keeping the intake of electrolytes and nutrients constant (see Table 46-9) allows systems to stabilize more quickly than adjusting intake in response to laboratory results.

Table 46-11 gives a recipe for the special rehydration solution used in severe malnutrition (ReSoMal). Therapeutic Combined Mineral Vitamin mix (CMV) contains electrolytes, minerals, and vitamins and is added to ReSoMal and feeds. If unavailable, potassium, magnesium, zinc, and copper can be added as an electrolyte/mineral stock solution (Table 46-12 provides a recipe) and a multivitamin supplement given separately.

- ***Rehabilitation***: The signals for entry to this phase are reduced/minimal edema and return of appetite.

A controlled transition over 3 days is recommended to prevent the "refeeding syndrome." After the transition,

Table 46-10 Recipes for Milk Formulas F75 and F100

	F75[b] (STARTER)	F75[c] (STARTER) (CEREAL-BASED)	F100[d] (CATCH-UP)
Dried skimmed milk (g)	25	25	80
Sugar (g)	100	70	50
Cereal flour (g)	—	35	—

Whisk at high speed to prevent oil from separating out.
[a]See Table 46-12 for recipe, or use commercially available therapeutic Combined Mineral Vitamin mix (CMV).
[b]A comparable F75 can be made from 35 g dried whole milk, 100 g sugar, 20 g oil, 20 mL electrolyte/mineral solution, and water to 1000 mL; or from 300 mL full cream cow's milk, 100 g sugar, 20 g oil, 20 mL electrolyte/mineral solution, and water to 1000 mL.
[c]This lower-osmolality formula may be helpful for children with dysentery or persistent diarrhea. Cook for 4 min.
[d]A comparable F100 can be made from 110 g dried whole milk, 50 g sugar, 30 g oil, 20 mL electrolyte/mineral solution, and water to 1000 mL; or from 880 mL full cream cow's milk, 75 g sugar, 20 g oil, 20 mL electrolyte/mineral solution, and water to 1000 mL.

Table 46-11 Recipe for Rehydration Solution for Malnutrition (ReSoMal)

INGREDIENT	AMOUNT
Water	2 L
WHO-ORS	One 1-L sachet*
Sucrose	50 g
Electrolyte/mineral solution†	mL

ReSoMal contains 37.5 mmol sodium and 40 mmol potassium/L
*Sachet contains 2.6 g sodium chloride, 2.9 g trisodium citrate, 1.5 g potassium chloride, 13.5 g glucose.
†See Table 46-12 for recipe, or use commercially available therapeutic Combined Mineral Vitamin mix (CMV).

Table 46-12 Recipe for Concentrated Electrolyte/Mineral Solution*

INGREDIENT	g	mol/20 mL
Potassium chloride: KCl	224.0	24 mmol
Tripotassium citrate	81.0	2 mmol
Magnesium chloride: $MgCl_2 . 6H_2O$	76.0	3 mmol
Zinc acetate: Zn acetate.$2H_2O$	8.2	300 μmol
Copper sulfate: $CuSO_4 . 5H_2O$	1.4	45 μmol
Water: make up to	2500 mL	

Add 20 mL when preparing 1 L of feed or ReSoMal.
*Make fresh each month. Use cooled boiled water.

unlimited amounts should be given of a high-energy, high-protein milk formula such as F100 (100 kcal and 3 g protein per 100 mL), or ready-to-use therapeutic food (RUTF), or family foods modified to have comparable energy and protein contents.

To make the transition, for 2 days replace F75 with an equal volume of F100 and then increase each successive feed by 10 mL until some feed remains uneaten (usually at around 200 mL/kg/day).

After the transition, give 150-220 kcal/kg/day and 4-6 g protein/kg/day and continue to give potassium, magnesium, and micronutrients. Add iron (3 mg/kg/day). If breastfed, encourage continued breastfeeding.

Children with severe malnutrition have developmental delays, so loving care, structured play, and sensory stimulation during and after treatment are essential to aid recovery of brain function.

Community-based treatment: Many children with severe acute malnutrition can be identified in their communities before medical complications arise. If these children have a good appetite and are clinically well, they can be rehabilitated at home through community-based therapeutic care, which has the added benefit of reducing their exposure to nosocomial infections and providing continuity of care after

recovery. It also reduces the time caregivers spend away from home and their opportunity costs, and can be cost-effective for health services.

Figure 46-7 shows the criteria for inpatient versus outpatient care. To maximize coverage and compliance, community-based therapeutic care has 4 main elements: community mobilization and sensitization; active case-finding; therapeutic care; and follow-up after discharge.

Community-based therapeutic care comprises steps 8-10, plus a broad-spectrum antibiotic (step 5). RUTF is usually provided, especially in times of food shortage. RUTF is specially designed for rehabilitating children with severe acute malnutrition at home. It is high in energy and protein and has electrolytes and micronutrients added. The most widely used RUTF is a thick paste that contains milk powder, peanuts, vegetable oil, and sugar. Pathogens cannot grow in it because of its low moisture content. Hospitalized children who have completed steps 1-7 and the transition can be transferred to community-based care for completion of their rehabilitation, thereby reducing their hospital stay to about 7-10 days.

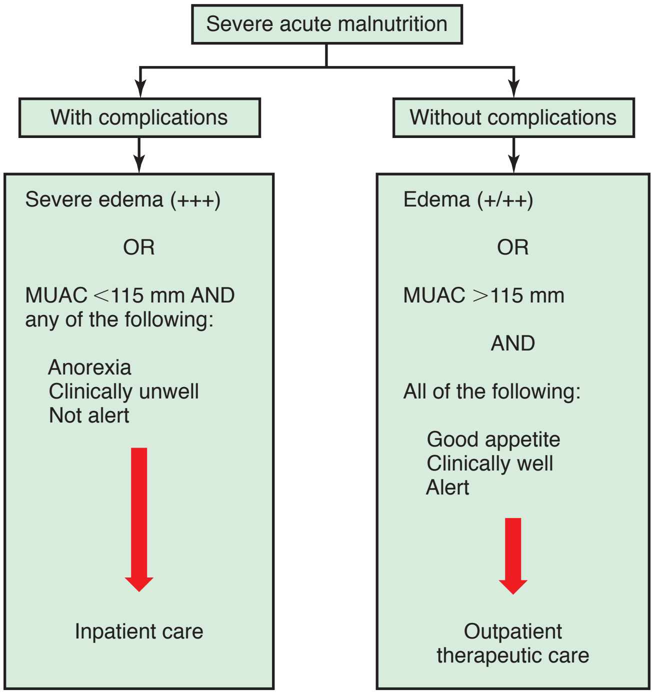

Figure 46-7 Flow diagram for inpatient and outpatient care in the child with severe acute malnutrition. MUAC, Mid upper arm circumference.

46.1 Refeeding Syndrome

Robert M. Kliegman

Refeeding syndrome can complicate the acute nutritional rehabilitation of children who are undernourished from any cause (Table 46-13). Refeeding syndrome is rare when the WHO recommendations for the treatment of malnutrition are followed (see Chapter 46); however, it may follow overly aggressive enteral or parenteral alimentation. Malnutrition usually has normal serum electrolytes but is associated with intracellular electrolyte depletion. When excessive carbohydrates are administered, the resultant increase in serum insulin levels may produce hypokalemia, hypophosphatemia, and hypomagnesemia. The hallmark of refeeding syndrome is the development of severe hypophosphatemia after the cellular uptake of phosphate during the 1st wk of starting to reefed. Serum phosphate levels of ≤0.5 mmol/L can produce weakness, rhabdomyolysis, neutrophil dysfunction, cardiorespiratory failure, arrhythmias, seizures, altered level of consciousness, or sudden death. Phosphate levels should be monitored during refeeding, and if they are low, phosphate should be administered during refeeding to treat severe hypophosphatemia (see Chapter 55.6).

Chapter **47**

Overweight and Obesity

Sheila Gahagan

Obesity is an important pediatric public health problem associated with risk of complications in childhood and increased morbidity and mortality throughout adult life.

EPIDEMIOLOGY

Obesity is a global public health problem, sparing only dramatically poor regions with chronic food scarcity such as sub-Saharan Africa and Haiti. In 2008, according to the World Health Organization, more than 1.4 billion persons ≥20 yr old were overweight or obese.

In the United States, 36% of adults are obese, and an additional 35% of adults are overweight. In children, the prevalence of obesity increased 300% over approximately 40 yr. The National Health and Nutrition Examination Survey, 2009-2010, found 32% of children, 2-19 yr old to be overweight or obese, and 17% in the obese range. Children's risk varies significantly by race/ethnicity. In 2009-2010, 24% of non-Hispanic Black, 21% of Hispanic, and >20% of American Indian/Alaskan Native children and adolescents were obese compared to 14% of white children. Across all racial groups, higher maternal education confers protection against childhood obesity.

Parental obesity correlates with a higher risk for obesity in their children. Prenatal factors including high preconceptual weight, gestational weight gain, high birth weight, and maternal smoking are associated with increased risk for later obesity. Paradoxically, intrauterine growth restriction with early infant catch-up growth is associated with the development of central adiposity and adult-onset cardiovascular risk. Breastfeeding is only modestly protective for obesity. Infants with high levels of negative reactivity (temperament) are at risk for obesity. Better self-regulation is protective.

BODY MASS INDEX

Obesity or increased adiposity is defined using the body mass index (BMI), which is an excellent proxy for more direct measurement of body fat. BMI = weight in kg/(height in meters)^2. Adults with a BMI ≥30 meet the criterion for obesity, and those with a BMI 25-30 fall in the overweight range. During childhood, levels of body fat change beginning with high adiposity during infancy. Body fat levels decrease for approximately 5.5 yr until the period called *adiposity rebound,* when body fat is typically at the lowest level. Adiposity then increases until early adulthood (Fig. 47-1). Consequently, obesity and overweight are defined using BMI percentiles; children >2 yr old with a BMI ≥95th percentile meet the criterion for obesity, and those with a BMI between the 85th and 95th percentiles fall in the overweight range.

ETIOLOGY

Humans have the capacity to store energy in adipose tissue, allowing improved survival in times of famine. Furthermore, humans innately prefer sweet and salty foods and reject bitter flavors. Many vegetables are bitter. These preferences probably reflect evolutionary adaptations to avoid consuming toxic plants. Nonetheless, repeated exposure to healthy foods promotes their acceptance and liking, especially in early life. Simplistically, obesity results from an imbalance of caloric intake and energy expenditure. Even incremental but sustained caloric excess results in excess adiposity. Individual adiposity is the result of a complex interplay among genetically determined body habitus, appetite, nutritional intake, physical activity, and energy expenditure. Environmental factors determine levels of available food, preferences for types of foods, levels of physical activity, and preferences for types of activities.

Environmental Changes

Over the last 4 decades, the food environment has changed dramatically. Changes in the food industry relate in part to social changes, as extended families have become more dispersed. Fewer families routinely prepare meals. Foods are increasingly prepared by a food industry, with high levels of calories, simple carbohydrates, and fat. The price of many foods has declined relative to the family budget. These changes, in combination with marketing pressure, have resulted in larger portion sizes and increased snacking between meals. The increased consumption of high-carbohydrate beverages, including sodas, sport drinks, fruit punch, and juice, adds to these factors.

One-third of U.S. children consume fast food daily. A typical fast food meal can contain 2000 kcal and 84 g of fat. Many children consume 4 servings of high-carbohydrate beverages per day, resulting in an additional 560 kcal of low nutritional value. Sweetened beverages have been linked to increased risk for obesity because children who drink high amounts of sugar do not consume less food. The dramatic increase in the use of high-fructose corn syrup to sweeten beverages and prepared foods is another important environmental change, leading to availability of inexpensive calories.

Since World War II, levels of physical activity in children and adults have declined. Changes in the built environment have resulted in more reliance on cars and decreased walking. Work is increasingly sedentary, and many sectors of society do not engage in physical activity during leisure time. For children, budgetary constraints and pressure for academic performance have led to less time devoted to physical education in schools. Perception of poor neighborhood safety is another factor that can lead to lower levels of physical activity when children are required to stay indoors. The advent of television, computers, and video games has resulted in opportunities for sedentary activities that do not burn calories.

Changes in another health behavior, sleep, might also contribute. Over the last 4 decades, children and adults have decreased the amount of time spent sleeping. Reasons for these changes may relate to increased time at work, increased time watching television, and a generally faster pace of life. Chronic partial sleep loss can increase risk for weight gain and obesity, with the impact possibly greater in children than in adults. In studies of young, healthy, lean men, short sleep duration was associated with decreased leptin levels and increased ghrelin levels, along with increased hunger and appetite. Sleep debt also results in decreased glucose tolerance and insulin sensitivity related to alterations in glucocorticoids and sympathetic activity. Some effects of sleep debt might relate to orexins, peptides synthesized in the lateral hypothalamus that can increase feeding, arousal, sympathetic activity, and/or neuropeptide Y activity.

Genetics

Genetic determinants also have a role in individual susceptibility to obesity (Table 47-1). Findings from genome-wide association studies explain a very small portion of interindividual variability in obesity. One important example, the *FTO* gene at 16q12, is associated with adiposity in childhood, probably explained by increased energy intake (Table 47-1). Monogenic forms of obesity have also been identified, including MC4R deficiency, associated with early-onset obesity and food-seeking behavior. In addition, there are genetic conditions associated with obesity, such as Prader-Willi syndrome, which results from absence of paternally expressed imprinted genes in the 15q11.2–q13 region. Prader-Willi syndrome is characterized by insatiable appetite and food seeking. Epigenetic environmental modification of genes may have a role in the development of obesity, especially during fetal and early life.

Endocrine and Neural Physiology

Monitoring of "stored fuels" and short-term control of food intake (appetite and satiety) occurs through neuroendocrine feedback loops linking adipose tissue, the gastrointestinal tract, and the central

Figure 47-1, cont'd

Table 47-1 Endocrine and Genetic Causes of Obesity

DISEASE	SYMPTOMS	LABORATORY
ENDOCRINE		
Cushing syndrome	Central obesity, hirsutism, moon face, hypertension	Dexamethasone suppression test
GH deficiency	Short stature, slow linear growth	Evoked GH response, IGF-1
Hyperinsulinism	Nesidioblastosis, pancreatic adenoma, hypoglycemia, Mauriac syndrome	Insulin level
Hypothyroidism	Short stature, weight gain, fatigue, constipation, cold intolerance, myxedema	TSH, FT_4
Pseudohypoparathyroidism	Short metacarpals, subcutaneous calcifications, dysmorphic facies, mental retardation, short stature, hypocalcemia, hyperphosphatemia	Urine cAMP after synthetic PTH infusion
GENETIC		
Alstrom syndrome	Cognitive impairment, retinitis pigmentosa, diabetes mellitus, hearing loss, hypogonadism, retinal degeneration	*ALMS1* gene
Bardet-Biedl syndrome	Retinitis pigmentosa, renal abnormalities, polydactyly, hypogonadism	*BBS1* gene
Biemond syndrome	Cognitive impairment, iris coloboma, hypogonadism, polydactyly	
Carpenter syndrome	Polydactyly, syndactyly, cranial synostosis, mental retardation	Mutations in the *RAB23* gene, located on chromosome 6 in humans
Cohen syndrome	Mid-childhood-onset obesity, short stature, prominent maxillary incisors, hypotonia, mental retardation, microcephaly, decreased visual activity	Mutations in the *VPS13B* gene (often called the *COH1* gene) at locus 8q22
Deletion 9q34	Early-onset obesity, mental retardation, brachycephaly, synophrys, prognathism, behavior and sleep disturbances	Deletion 9q34
Down syndrome	Short stature, dysmorphic facies, mental retardation	Trisomy 21
ENPP1 gene mutations	Insulin resistance, childhood obesity	Gene mutation on chromosome 6q
Fröhlich syndrome	Hypothalamic tumor	
FTO gene polymorphism	Dysregulation of orexigenic hormone acyl-ghrelin, poor postprandial appetite suppression	Homozygous for *FTO* AA allele
Leptin or leptin receptor gene deficiency	Early-onset severe obesity, infertility (hypogonadotropic hypogonadism)	Leptin
Melanocortin 4 receptor gene mutation	Early-onset severe obesity, increased linear growth, hyperphagia, hyperinsulinemia Most common known genetic cause of obesity Homozygous worse than heterozygous	*MC4R* mutation
Prader-Willi Syndrome	Neonatal hypotonia, slow infant growth, small hands and feet, mental retardation, hypogonadism, hyperphagia leading to severe obesity, paradoxically elevated ghrelin	Partial deletion of chromosome 15 or loss of paternally expressed genes
Proopiomelanocortin deficiency	Obesity, red hair, adrenal insufficiency, hyperproinsulinemia	Loss-of-function mutations of the *POMC* gene
Rapid-onset obesity with hypothalamic dysfunction, hypoventilation, and autonomic dysregulation (ROHHAD)	Often confused with congenital central hypoventilation syndrome (CCHS), presentation ≥1.5 yr with weight gain, hyperphagia, hypoventilation, cardiac arrest, central diabetes insipidus, hypothyroidism, growth hormone deficiency, pain insensitivity, hypothermia, precocious puberty, neural crest tumors	Unknown genes May be a paraneoplastic disorder
Turner syndrome	Ovarian dysgenesis, lymphedema, web neck, short stature, cognitive impairment	XO chromosome

cAMP, cyclic adenosine monophosphate; FT_4, free thyroxine; GH, growth hormone; IGF, insulin-like growth factor; PTH, parathyroid hormone; TSH, thyroid-stimulating hormone.

nervous system (Fig. 47-2). Gastrointestinal hormones, including cholecystokinin, glucagon-like peptide-1, peptide YY, and vagal neuronal feedback promote satiety. Ghrelin stimulates appetite. Adipose tissue provides feedback regarding energy storage levels to the brain through hormonal release of adiponectin and leptin. These hormones act on the arcuate nucleus in the hypothalamus and on the solitary tract nucleus in the brainstem and, in turn, activate distinct neuronal networks. Adipocytes secrete adiponectin into the blood, with reduced levels in response to obesity and increased levels in response to fasting. Reduced adiponectin levels are associated with lower insulin sensitivity and adverse cardiovascular outcomes. Leptin is directly involved in satiety, as low leptin levels stimulate food intake and high leptin levels inhibit hunger in animal models and in healthy human volunteers. Adiposity correlates to serum leptin levels among children and adults, with the direction of effect remaining unclear.

Numerous neuropeptides in the brain, including peptide YY, agouti-related peptide, and orexin, appear to affect appetite stimulation, whereas melanocortins and α-melanocortin–stimulating hormone are involved in satiety. The neuroendocrine control of appetite and weight involves a negative-feedback system, balanced between short-term control of appetite and long-term control of adiposity (including leptin). Peptide YY reduces food intake via the vagal–brainstem–hypothalamic pathway. Developmental changes in peptide YY are evident as infants have higher levels of peptide YY than school-age children and adults. Obese children have lower fasting levels of peptide YY compared to adults. Weight loss may restore levels of peptide YY in children even though this does not happen in adults. In addition, patients homozygous for the *FTO* obesity risk allele demonstrate poor regulation of the orexigenic hormone acyl-ghrelin and have poor postprandial appetite suppression.

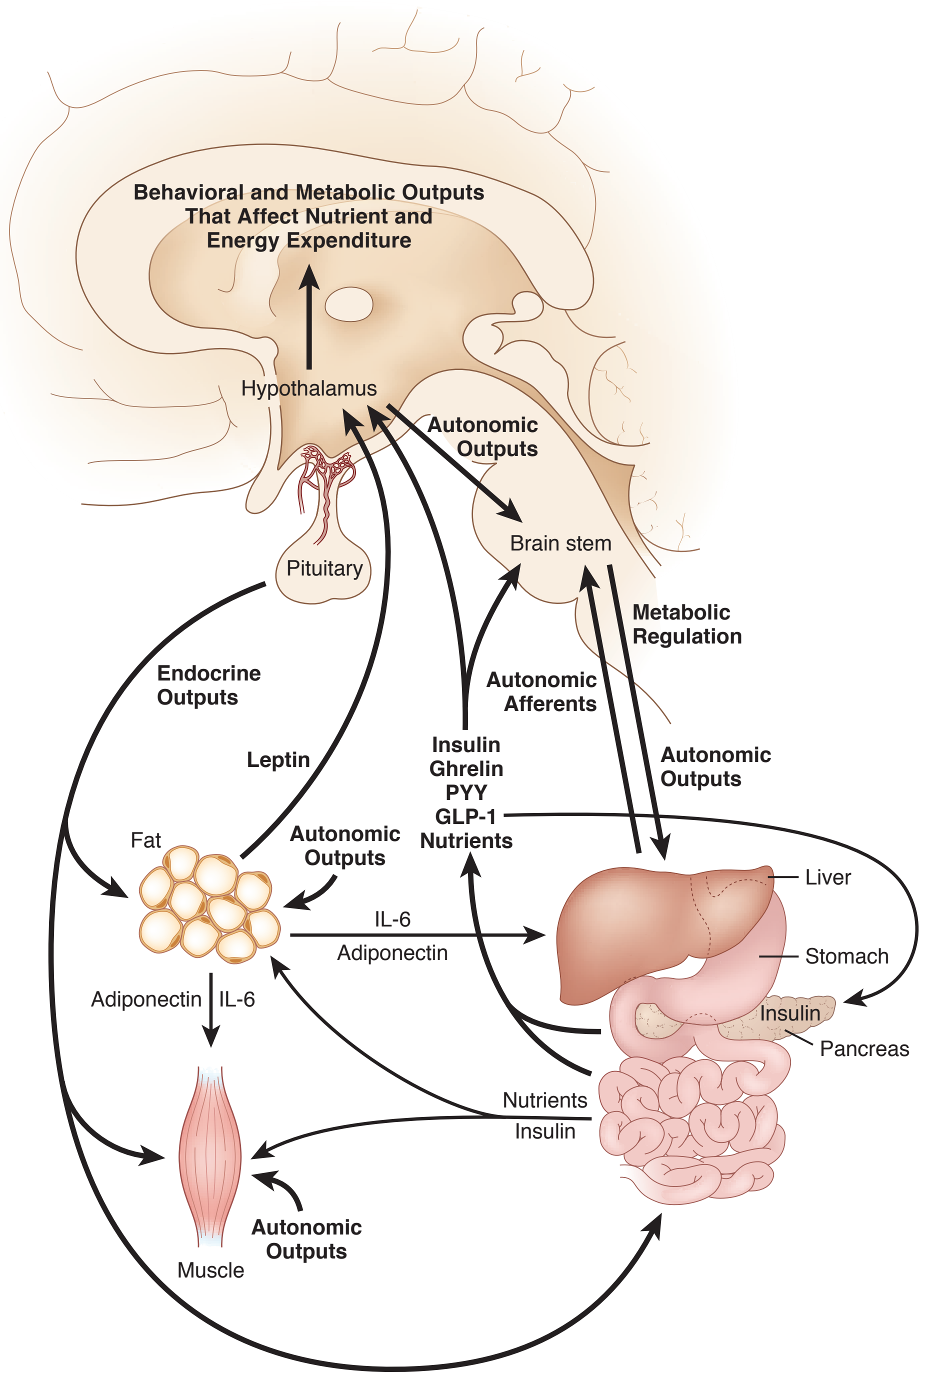

Figure 47-2 **Regulation of energy homeostasis by the brain–adipose tissue–intestinal axis.** Leptin stimulates hypothalamic anorexigenic and inhibits orexigenic neurons. Adiponectin stimulates hepatic, and muscle glucose utilization and increases insulin sensitivity, while interleukin-6 (IL-6) contributes to adipose tissue, muscle and hepatic insulin resistance. Peptide YY (PYY) inhibits orexigenic and glucagon-like peptide 1 (GLP-1) stimulates anorexigenic hypothalamic neurons. GLP-1 also augments glucose stimulated pancreatic insulin secretion and suppresses glucagon secretion. Insulin stimulates adipose tissue and muscle glucose uptake, enhances lipogenesis, suppresses hepatic glucose production, and has an inhibitory effect on the hypothalamic anorexigenic system. Ghrelin stimulates the orexigenic hypothalamic pathways. *(Modified from Melmed S, Polonsky KS, Larsen PR, Kronenberg HM:* Williams Textbook of Endocrinology*, ed 12, Philadelphia, 2011, Saunders.* Fig. 35-1.*)*

COMORBIDITIES

Complications of pediatric obesity occur during childhood and adolescence and persist into adulthood. An important reason to prevent and treat pediatric obesity is the increased risk for morbidity and mortality later in life. The Harvard Growth Study found that boys who were overweight during adolescence were twice as likely to die from cardiovascular disease as those who had normal weight. More immediate comorbidities include type 2 diabetes, hypertension, hyperlipidemia, and nonalcoholic fatty liver disease (Table 47-2). Insulin resistance increases with increasing adiposity and independently affects lipid metabolism and cardiovascular health. The metabolic syndrome (central obesity, hypertension, glucose intolerance, and hyperlipidemia) increases risk for cardiovascular morbidity and mortality. Nonalcoholic fatty liver disease (NAFLD) occurs in 10-25% of obese

Table 47-2 Obesity-Associated Comorbidities

DISEASE	POSSIBLE SYMPTOMS	LABORATORY CRITERIA
CARDIOVASCULAR		
Dyslipidemia	HDL <40, LDL >130, total cholesterol >200	Fasting total cholesterol, HDL, LDL, triglycerides
Hypertension	SBP >95% for sex, age, height	Serial testing, urinalysis, electrolytes, blood urea nitrogen, creatinine
ENDOCRINE		
Type 2 diabetes mellitus	Acanthosis nigrans, polyuria, polydipsia	Fasting blood glucose >110, hemoglobin A_{1c}, insulin level, C-peptide, oral glucose tolerance test
Metabolic syndrome	Central adiposity, insulin resistance, dyslipidemia, hypertension, glucose intolerance	Fasting glucose, LDL and HDL cholesterol
Polycystic ovary syndrome	Irregular menses, hirsutism, acne, insulin resistance, hyperandrogenemia	Pelvic ultrasound, free testosterone, LH, FSH
GASTROINTESTINAL		
Gallbladder disease	Abdominal pain, vomiting, jaundice	Ultrasound
Nonalcoholic fatty liver disease (NAFLD)	Hepatomegaly, abdominal pain, dependent edema, ↑ transaminases Can progress to fibrosis, cirrhosis	AST, ALT, ultrasound, CT, or MRI
NEUROLOGIC		
Pseudotumor cerebri	Headaches, vision changes, papilledema	Cerebrospinal fluid opening pressure, CT, MRI
Migraines	Hemicrania, headaches	None
ORTHOPEDIC		
Blount disease (tibia vara)	Severe bowing of tibia, knee pain, limp	Knee x-rays
Musculoskeletal problems	Back pain, joint pain, frequent strains or sprains, limp, hip pain, groin pain, leg bowing	X-rays
Slipped capital femoral epiphysis	Hip pain, knee pain, limp, decreased mobility of hip	Hip x-rays
PSYCHOLOGICAL		
Behavioral complications	Anxiety, depression, low self-esteem, disordered eating, signs of depression, worsening school performance, social isolation, problems with bullying or being bullied	Child Behavior Checklist, Children's Depression Inventory, Peds QL, Eating Disorder Inventory 2, subjective ratings of stress and depression, Behavior Assessment System for Children, Pediatric Symptom Checklist
PULMONARY		
Asthma	Shortness of breath, wheezing, coughing, exercise intolerance	Pulmonary function tests, peak flow
Obstructive sleep apnea	Snoring, apnea, restless sleep, behavioral problems	Polysomnography, hypoxia, electrolytes (respiratory acidosis with metabolic alkalosis)

adolescents. NAFLD is now the most common chronic liver disease in U.S. children and adolescents. It can present with advanced fibrosis or nonalcoholic steatohepatitis and may result in cirrhosis and hepatocellular carcinoma. Insulin resistance is commonly associated. Furthermore, NAFLD is independently associated with increased risk of cardiovascular disease.

Obesity may also be associated with chronic inflammation. Adiponectin, a peptide with antiinflammatory properties, occurs in reduced levels in obese patients as compared to insulin-sensitive, lean persons. Low adiponectin levels correlate with elevated levels of free fatty acids and plasma triglycerides as well as a high BMI, and high adiponectin levels correlate with peripheral insulin sensitivity. Adipocytes secrete peptides and cytokines into the circulation, and proinflammatory peptides such interleukin (IL)-6 and tumor necrosis factor-α (TNF-α) occur in higher levels in obese patients. Specifically, IL-6 stimulates production of C-reactive protein in the liver. C-reactive protein is a marker of inflammation and might link obesity, coronary disease, and subclinical inflammation.

Some complications of obesity are mechanical, including obstructive sleep apnea and orthopedic complications. Orthopedic complications include Blount disease and slipped femoral capital epiphysis (see Chapters 677, 678.4).

Mental health problems can coexist with obesity, with the possibility of bidirectional effects. These associations are modified by gender, ethnicity, and socioeconomic status. Self-esteem may be lower in obese adolescent girls compared to nonobese peers. Some studies have found an association between obesity and adolescent depression. There is considerable interest in the cooccurrence of eating disorders and obesity.

IDENTIFICATION

Overweight and obese children are often identified as part of routine medical care, and the child and family may be unaware that the child has increased adiposity. They may be unhappy with the medical provider for raising this issue and respond with denial or apparent lack of concern. It is often necessary to begin by helping the family understand the importance of healthy weight for current and future health, especially because intervention requires considerable effort by the child and the family. Forging a good therapeutic relationship is important, because obesity intervention requires a chronic disease management approach. Successful resolution of this problem necessitates considerable family and child effort over an extended period in order to change eating and activity behaviors.

EVALUATION

The evaluation of the overweight or obese child begins with examination of the growth chart for weight, height, and BMI trajectories; consideration of possible medical causes of obesity; and detailed

exploration of family eating, nutritional, and activity patterns. A complete pediatric history is used to uncover comorbid disorders. The family history focuses on the adiposity of other family members and the family history of obesity-associated disorders. The physical examination adds data that can lead to important diagnoses. Laboratory testing is guided by the need to identify comorbid conditions.

Examination of the growth chart reveals the severity, duration, and timing of obesity onset. Children who are overweight (BMI in the 85th-95th percentile) are less likely to have developed comorbid conditions than those who are obese (BMI ≥95th percentile). Those with a BMI ≥99th percentile are even more likely to have coexisting medical problems. Once obesity severity is determined, the BMI trajectory is examined to elucidate when the child became obese. Several periods during childhood are considered sensitive periods or times of increased risk for developing obesity, including infancy, adiposity rebound (when body fat is lowest at approximately age 5.5 yr), and adolescence. An abrupt change in BMI might signal the onset of a medical problem or a period of family or personal stress for the child. Examination of the weight trajectory can further expand understanding of how the problem developed. A young child might exhibit high weight and high height because linear growth can increase early in childhood if a child consumes excess energy. At some point, the weight percentile exceeds the height percentile and the child's BMI climbs into the obese range. Another example is a child whose weight rapidly increases when she reduces her activity level and consumes more meals away from home. Examination of the height trajectory can reveal endocrine problems, which often occur with slowing of linear growth.

Consideration of possible medical causes of obesity is essential, even though endocrine and genetic causes are rare (see Table 47-1). Growth hormone deficiency, hypothyroidism, and Cushing syndrome are examples of endocrine disorders that can lead to obesity. In general, these disorders manifest with slow linear growth. Because children who consume excessive amounts of calories tend to experience accelerated linear growth, short stature warrants further evaluation. Genetic disorders associated with obesity can have coexisting dysmorphic features, cognitive impairment, vision and hearing abnormalities, or short stature. In some children with congenital disorders such as myelodysplasia or muscular dystrophy, lower levels of physical activity can lead to secondary obesity. Some medications can cause excessive appetite and hyperphagia, resulting in obesity. Atypical antipsychotic medications often have this dramatic side effect. Rapid weight gain in a child or adolescent taking one of these medications might require a discontinuation of that medication. Poor linear growth and rapid changes in weight gain are indications for evaluation of possible medical causes.

Exploration of family eating and nutritional and activity patterns begins with a description of regular meal and snack times and family habits for walking, bicycle riding, active recreation, television, computer, and video game time. It is useful to request a 24-hr dietary recall with special attention to intake of fruits, vegetables, and water, as well as high-calorie foods and high-carbohydrate beverages. When possible, evaluation by a nutritionist is extremely helpful. This information will form the basis for incremental changes in eating behavior, caloric intake, and physical activity during the intervention.

Initial assessment of the overweight or obese child includes a complete review of bodily systems focusing on the possibility of comorbid conditions (see Table 47-2). Developmental delay and visual and hearing impairment can be associated with genetic disorders. Difficulty sleeping, snoring, or daytime sleepiness suggests the possibility of sleep apnea. Abdominal pain might suggest NAFLD. Symptoms of polyuria, nocturia, or polydipsia may be the result of type 2 diabetes. Hip or knee pain can be caused by secondary orthopedic problems, including Blount disease and slipped capital femoral epiphysis. Irregular menses may be associated with polycystic ovary syndrome. Acanthosis nigricans can suggest insulin resistance and type 2 diabetes (Fig. 47-3).

The family history begins with identifying other obese family members. Parental obesity is an important risk for child obesity. If all family members are obese, focusing the intervention on the entire family is reasonable. The child may be at increased risk for developing type 2 diabetes if a family history exists. Patients of African-American, Hispanic, or Native American heritage are also at increased risk for developing type 2 diabetes. Identification of a family history of hypertension, cardiovascular disease, or metabolic syndrome indicates increased risk for developing these obesity-associated conditions. If one helps the family to understand that childhood obesity increases risk for developing these chronic diseases, this educational intervention might serve as motivation to improve their nutrition and physical activity.

Figure 47-3 Acanthosis nigricans. *(From Gahagan S: Child and adolescent obesity,* Curr Probl Pediatr Adolesc Health Care *34:6–43, 2004.)*

Physical examination should be thorough, focusing on possible comorbid conditions (see Table 47-2). Careful screening for hypertension using an appropriately sized blood pressure cuff is important. Systematic examination of the skin can reveal acanthosis nigricans, suggesting insulin resistance, or hirsutism, suggesting polycystic ovary syndrome. Tanner staging can reveal premature adrenarche secondary to advanced sexual maturation in overweight and obese girls.

Laboratory testing for fasting plasma glucose, triglycerides, low-density lipoprotein and high-density lipoprotein cholesterol, and liver function tests are recommended as part of the initial evaluation for newly identified pediatric obesity (Table 47-3). Overweight children (BMI 85th-95th percentile) who have a family history of diabetes mellitus or signs of insulin resistance should also be evaluated with a fasting plasma glucose test. Other laboratory testing should be guided by history or physical examination findings.

INTERVENTION

There is evidence that some interventions result in modest but significant and sustained improvement in body mass. Based on behavior change theories, treatment includes specifying target behaviors, self-monitoring, goal setting, stimulus control, and promotion of self-efficacy and self-management skills. Behavior changes associated with improving BMI include drinking lower quantities of sugar-sweetened beverages, consuming higher-quality diets, increasing exercise, watching less TV, and self-weighing. Most successful interventions have been family based and take into account the child's developmental age. "Parent-only" treatment can be as effective as "parent–child" treatment. Because obesity is multifactorial, not all children and adolescents will respond to the same approach. For example, "loss-of-control" eating, associated with weight gain and obesity, predicts poor outcome in response to family-based treatment. Furthermore, clinical-treatment programs are expensive and not widely available. Therefore there is interest in novel approaches including Internet-based treatments and guided self-help.

It is important to begin with clear recommendations about appropriate caloric intake for the obese child (Table 47-4). Working with a dietitian is very helpful. Meals should be based on fruits, vegetables, whole grains, lean meat, fish, and poultry. Prepared foods should be chosen for their nutritional value, with attention to calories and fat. Foods that provide excessive calories and low nutritional value should be reserved for infrequent treats.

Weight-reduction diets in adults generally do not lead to sustained weight loss. Therefore, the focus should be on changes that can be maintained for life. Attention to eating patterns is helpful. Families should be encouraged to plan family meals, including breakfast. It is almost impossible for a child to make changes in nutritional intake and eating patterns if other family members do not make the same changes. Dietary needs also change developmentally, as adolescents require greatly increased calories during their growth spurts, and adults who lead inactive lives need fewer calories than active and growing children.

Table 47-3 Normal Laboratory Values for Recommended Tests

LABORATORY TEST	NORMAL VALUE
Glucose	<110 mg/dL
Insulin	<15 mU/L
Hemoglobin A_{1c}	<5.7%
AST (age 2-8 yr)	<58 U/L
AST (age 9-15 yr)	<46 U/L
AST (age 15-18 yr)	<35 U/L
ALT	<35 U/L
Total cholesterol	<170 mg/dL
LDL	<110 mg/dL
HDL	>45 mg/dL
Triglycerides (age 0-9 yr)	<75 mg/dL
Triglycerides (age 10-19 yr)	<90 mg/dL

AST, aspartate aminotransferase; ALT, alanine aminotransferase; LDL, low-density lipoprotein; HDL, high-density lipoprotein.

From Children's Hospital of Wisconsin: The NEW (nutrition, exercise and weight management) kids program *(PDF file). http://www.chw.org/display/displayFile.asp?docid=33672&filename=/Groups/NEWKids/NewKidsReferral.PDF.*

Psychological strategies are helpful. The "traffic light" diet groups foods into those that can be consumed without any limitations (green), in moderation (yellow), or reserved for infrequent treats (red) (Table 47-5). The concrete categories are very helpful to children and families. This approach can be adapted to any ethnic group or regional cuisine. Motivational interviewing begins with assessing how ready the patient is to make important behavioral changes. The professional then engages the patient in developing a strategy to take the next step toward the ultimate goal of healthy nutritional intake. This method allows the professional to take the role of a coach, helping the child and family reach their goals. Other behavioral approaches include family rules about where food may be consumed; for example, "not in the bedroom."

Increasing physical activity without decreasing caloric intake is unlikely to result in weight loss. Nonetheless, it can increase aerobic fitness and decrease percent body fat even without weight loss. Therefore, increasing physical activity can decrease risk for cardiovascular disease, improve well-being, and contribute to weight loss. Increased physical activity can be accomplished by walking to school, engaging in physical activity during leisure time with family and friends, or enrolling in organized sports. Children are more likely to be active if their parents are active. Just as family meals are recommended, family physical activity is recommended.

Active pursuits can replace more sedentary activities. The American Academy of Pediatrics recommends that screen time be restricted to no more than 2 hr/day for children >2 yr old and that children <2 yr old not watch television. Television watching is often associated with eating, and many highly caloric food products are marketed directly to children during child-oriented television programs.

Pediatric providers should assist families to develop goals to change nutritional intake and physical activity. They can also provide the child and family with needed information. The family should not expect immediate lowering of BMI percentile related to behavioral changes but can instead count on a gradual decrease in the rate of BMI percentile increase until it stabilizes, followed by a gradual decrease in BMI percentile. Referral to multidisciplinary, comprehensive pediatric weight-management programs is ideal for obese children whenever possible.

There is no effective pharmacotherapy resulting in reversal of excess adiposity in children and adolescents. Available medications result in

Table 47-4 Recommended Caloric Intake Designated by Age and Gender

LIFE-STAGE GROUP	AGE (yr)	RELATIVELY SEDENTARY LEVEL OF ACTIVITY (kcal)	MODERATE LEVEL OF ACTIVITY (kcal)	ACTIVE (kcal)
Child	2-3	1,000	1,000-1,400	1,000-1,400
Female	4-8	1,200	1,400-1,600	1,400-1,800
	9-13	1,600	1,600-2,000	1,800-2,200
	14-18	1,800	2,000	2,400
Male	4-8	1,400	1,400-1,600	1,600-2,000
	9-13	1,800	1,800-2,200	2,000-2,600
	14-18	2,200	2,400-2,800	2,800-3,200

Table 47-5 Traffic Light Diet Plan

FEATURE	GREEN LIGHT FOODS	YELLOW LIGHT FOODS	RED LIGHT FOODS
Quality	Low-calorie, high-fiber, low-fat, nutrient-dense	Nutrient-dense, but higher in calories and fat	High in calories, sugar, and fat
Types of food	Fruits, vegetables	Lean meats, dairy, starches, grains	Fatty meats, sugar, sugar-sweetened beverages, fried foods
Quantity	Unlimited	Limited	Infrequent or avoided

modest weight loss or BMI improvement even when combined with behavioral interventions. Various classes of drugs are of interest, including those that decrease energy intake or act centrally as anorexiants, those that affect the availability of nutrients through intestinal or renal tubular reabsorption, and those that affect metabolism. The only U.S. Food and Drug Administration (FDA)-approved medication for obesity in children <16 yr old is orlistat, which decreases absorption of fat, resulting in modest weight loss. Complications include flatulence, oily stools, and spotting. This agent offers little benefit to severely obese adolescents. Because there are multiple redundant neural mechanisms that act to protect body weight, promoting weight loss is extremely difficult. For this reason, there is considerable interest in combining therapies that simultaneously target multiple weight-regulating pathways. One example, approved for adults, combines phentermine, a noradrenergic agent, with topiramate, a γ-aminobutyric acid (GABA)-ergic medication. This combination resulted in a mean 10.2-kg weight loss compared to 1.4 kg in the placebo group. Side effects are common and include dry mouth, constipation, paresthesias, insomnia, and cognitive dysfunction. Another promising example is the combination of amylin (decreases food intake and slows gastric emptying) with leptin (which has no anorexigenic effects when given alone). This combination requires injection and is in clinical trials in adults. Another FDA approved (for adults) drug is lorcaserin, a selective serotonin 2C receptor agonist. Establishing long-term safety and tolerability in children is a challenge as medications of interest have central nervous system effects or interfere with absorption of nutrients; teratologic effects must be considered for use in adolescent girls.

In some cases, it is reasonable to refer adolescents for evaluation for bariatric surgery. The American Pediatric Surgical Association Guidelines recommends that surgery be considered only in children with complete or near-complete skeletal maturity, a BMI ≥40, and a medical complication resulting from obesity, *after* they have failed 6 mo of a multidisciplinary weight management program. Surgical approaches include the Roux-en-Y and the adjustable gastric band. In obese adults, bariatric surgery reduces the risk of developing type 2 diabetes mellitus. In obese adult patients with existing type 2 diabetes, bariatric surgery improves the control of diabetes.

PREVENTION

Prevention of child and adolescent obesity is essential for public health in the United States and most other countries (Table 47-6 and 47-7). Efforts by pediatric providers can supplement national- and community-level public health programs. The National Institutes of Health and Centers for Disease Control and Prevention recommend a variety of initiatives to combat the current obesigenic environment, including promotion of breastfeeding, access to fruits and vegetables, walkable communities, and 60 min/day of activity for children. The U.S. Department of Agriculture sponsors programs promoting 5.5 cups of fruits and vegetables per day. Incentives for the food industry to promote consumption of healthier foods should be considered. Marketing of unhealthy foods to children has begun to be regulated. We expect to see changes in federal food programs including commodity foods, the Women, Infant, and Children Supplemental Food Program, and school-lunch programs to meet the needs of today's children.

Pediatric prevention efforts begin with careful monitoring of weight and BMI percentiles at healthcare maintenance visits. Attention to changes in BMI percentiles can alert the pediatric provider to increasing adiposity before the child becomes overweight or obese. All families should be counseled about healthy nutrition for their children because the current prevalence of overweight and obesity in adults is 65%. Therefore, approximately two-thirds of all children can be considered at risk for becoming overweight or obese at some time in their lives. Those who have an obese parent are at increased risk. Prevention efforts begin with promotion of exclusive breastfeeding for 6 mo and total breastfeeding for 12 mo. Introduction of infant foods at 6 mo should focus on cereals, fruits, and vegetables. Lean meats, poultry, and fish may be introduced later in the 1st year of life. Parents should be specifically counseled to avoid introducing highly sugared beverages and foods in the 1st year of life. Instead, they should expose their infants and young children to a rich variety of fruits, vegetables, grains, lean meats, poultry, and fish to facilitate acceptance of a diverse and healthy diet. Parenting matters, and authoritative parents are more likely to have children with a healthy weight than those who are authoritarian or permissive. Families who eat regularly scheduled meals together are less likely to have overweight or obese children. Child health professionals are able to address a child's nutritional status and to provide expertise in child growth and development.

Child health professionals can also promote physical activity during regular healthcare maintenance visits. Parents who spend some of their leisure time in physical activity promote healthy weight in their children. Beginning in infancy, parents should be cognizant of their child's developmental capability and need for physical activity. Because television, computer, and video game time can replace health-promoting physical activity, physicians should counsel parents to limit screen time for their children. Snacking during television watching should be discouraged. Parents can help their children to understand that television commercials intend to sell a product. Children can learn that their parents will help them by responsibly choosing healthy foods.

As obesity is determined by complex multifactorial conditions, prevention will take efforts at multiple levels of social organization. One example, EPODE (Ensemble Prévenons l'Obésité Des Enfants), is a multilevel prevention strategy, which began in France and has been adopted by more than 500 communities in 6 countries. The goal is for local environments, daycare centers, schools, recreational settings and families to adopt practices that promote healthy lifestyles for children from birth to 12 yr old. This initiative relies on 4 necessary components: political commitment to change, resources to support social marketing and changes, support services, evidence-based practices. All EPODE sites include monitoring and evaluation. Similar efforts are taking place in the United States. An example of a U.S. community effort is Shape Up Somerville, a citywide campaign to increase daily physical activity and healthy eating in Somerville, MA, which has been ongoing since 2002. This systems intervention focuses on school health curricula, healthier food in schools and restaurants, safe routes to school, walkable and bikeable streets and worksite wellness. Communitywide programs are important because neighborhood environmental factors (poverty) have been associated with obesity in its residents. Although these efforts have resulted in lower weight gain in older children and adolescents, there is considerable interest in focusing earlier in the life cycle. Beginning obesity prevention during pregnancy and engaging health systems, early childhood programs, and community systems to support healthier life cycles is an approach with tremendous promise.

Bibliography is available at Expert Consult.

Table 47-6	Proposed Suggestions for Preventing Obesity

PREGNANCY
Normalize body mass index before pregnancy.
Do not smoke.
Maintain moderate exercise as tolerated.
In gestational diabetics, provide meticulous glucose control.
Gestational weight gain within the Institute of Medicine (IOM) recommendations.

POSTPARTUM AND INFANCY
Breastfeeding: exclusive for 4-6 mo, continue with other foods for 12 mo.
Postpone the introduction of baby foods to 4-6 mo and juices to 12 mo.

FAMILIES
Eat meals as a family in a fixed place and time.
Do not skip meals, especially breakfast.
No television during meals.
Use small plates, and keep serving dishes away from the table.
Avoid unnecessary sweet or fatty foods and sugar-sweetened drinks.
Remove televisions from children's bedrooms; restrict times for television viewing and video games.
Do not use food as a reward.

SCHOOLS
Eliminate candy and cookie sales as fundraisers.
Review the contents of vending machines and replace with healthier choices; eliminate sodas.
Avoid financial support for sports teams from beverage and food industries.
Install water fountains and hydration stations.
Educate teachers, especially physical education and science faculty, about basic nutrition and the benefits of physical activity.
Educate children from preschool through high school on appropriate diet and lifestyle.
Mandate minimum standards for physical education, including 60 min of strenuous exercise 5 times weekly.
Encourage "the walking school bus": groups of children walking to school with adult supervision.

COMMUNITIES
Increase family-friendly exercise and safe play facilities for children of all ages.
Develop more mixed residential-commercial developments for walkable and bicyclable communities.
Discourage the use of elevators and moving walkways.
Provide information on how to shop and prepare healthier versions of culture-specific foods.

HEALTHCARE PROVIDERS
Explain the biologic and genetic contributions to obesity.
Give age-appropriate expectations for body weight in children.
Work toward classifying obesity as a disease to promote recognition, reimbursement for care, and willingness and ability to provide treatment.

INDUSTRY
Mandate age-appropriate nutrition labeling for products aimed at children (e.g., red light/green light foods, with portion sizes).
Encourage marketing of interactive video games in which children must exercise in order to play.
Use celebrity advertising directed at children for healthful foods to promote breakfast and regular meals.
Reduce portion size (drinks and meals).

GOVERNMENT AND REGULATORY AGENCIES
Classify childhood obesity as a legitimate disease.
Find novel ways to fund healthy lifestyle programs (e.g., with revenues from food and drink taxes).
Subsidize government-sponsored programs to promote the consumption of fresh fruits and vegetables.
Provide financial incentives to industry to develop more healthful products and to educate the consumer on product content.
Provide financial incentives to schools that initiate innovative physical activity and nutrition programs.
Allow tax deductions for the cost of weight loss and exercise programs.
Provide urban planners with funding to establish bicycle, jogging, and walking paths.
Ban advertising of fast foods, nonnutritious foods, and sugar-sweetened beverages directed at preschool children, and restrict advertising to school-age children.
Ban toys as gifts to children for purchasing fast foods.

Table 47-7	Anticipatory Guidance: Establishing Healthy Eating Habits in Children

Do not punish a child during mealtimes with regard to eating. The emotional atmosphere of a meal is very important. Interactions during meals should be pleasant and happy.
Do not use foods as rewards.
Parents, siblings, and peers should model healthy eating, tasting new foods, and eating a well-balanced meal.
Children should be exposed to a wide range of foods, tastes, and textures.
New foods should be offered multiple times. Repeated exposure leads to acceptance and liking.
Forcing a child to eat a certain food will decrease the child's preference for that food. Children's wariness of new foods is normal and should be expected. Offering a variety of foods with low-energy density helps children balance energy intake.
Parents should control what foods are in the home. Restricting access to foods in the home will increase rather than decrease a child's desire for that food.
Children tend to be more aware of satiety than adults, so allow children to respond to satiety, and stop eating. Do not force children to "clean their plate."

Chapter 48

Vitamin A Deficiencies and Excess

A. Catharine Ross and Libo Tan

OVERVIEW OF VITAMIN A

Vitamin A is a fat-soluble micronutrient that cannot be synthesized de novo by the mammalian body, thus it is an obligatory dietary factor. The term vitamin A is generally used to refer to a group of compounds that possess the biologic activity of *all-trans* retinol (Fig. 48-1). As a fat-soluble micronutrient, vitamin A is recognized as being essential for all vertebrates for normal vision, reproduction, cell and tissue differentiation, and functions of the immune system. Vitamin A plays critical roles in neonatal development. It is required for normal embryonic development, hematopoiesis, immune response, metabolism, and growth and differentiation of many types of cells.

Vitamin A can be obtained from the diet where its main form is as retinyl esters, such as retinyl palmitate, which are called preformed vitamin A. They are found primarily in certain foods of animal origin. Organ meats (especially liver, kidney) are very rich in vitamin A, while other meats, milk, and cheese contain moderate levels. Other sources of vitamin A include several provitamin A carotenoids, which are found naturally in many fruits and vegetables, especially yellow-orange vegetables (pumpkin, squash, sweet potato), and leafy green vegetables (chard, spinach, broccoli). One of the most abundant carotenoids is β-carotene. α-Carotene and β-cryptoxanthin also possess vitamin A activity at a lower bioactivity. In the body, these precursors are used for the synthesis of 2 essential metabolites of vitamin A. One is *all-trans* retinoic acid, the form of vitamin A required for cell differentiation and the regulation of gene transcription. It is the most bioactive form of vitamin A. The other is *11-cis* retinal, required for vision. It functions as the light-absorbing chromophore of the visual pigments rhodopsin and iodopsin.

METABOLISM OF VITAMIN A

Ingested retinyl esters must first be hydrolyzed in the intestinal lumen, a process that liberates unesterified retinol, for the absorption of vitamin A. Most of the retinol is then reesterified in the enterocytes. The absorption of preformed vitamin A is very efficient. Approximately 70-90% of dietary preformed vitamin A is absorbed as long as there is ~10 g or more fat in the meal. Chronic intestinal disorders or lipid malabsorption can result in vitamin A deficiency. Uncleaved provitamin-A carotenoids in the intestine are also incorporated into chylomicrons and delivered to various tissues. The estimated absorption efficiency of carotenoids is approximately 20-50%, and appears to be more variable among individuals than for preformed vitamin A. The efficiency of conversion of B-carotene to retinol is much lower than expected. The carotene cleavage enzyme β-carotene monooxygenase, present in the enterocyte, exhibits certain single nucleotide polymorphisms that reduce the efficiency of conversion of β-carotene to retinol.

Once retinol is esterified in the enterocyte, retinyl ester is then packaged into nascent chylomicrons, which are then secreted into the lymphatic vessels and transported via the circulation to the liver or to other tissues. When vitamin A status is adequate, most mammals, including humans, store most of their total body vitamin A in the liver, within stellate cells. When their vitamin A status is deficient, vitamin A stores can be mobilized; the released retinol can be used by extrahepatic tissues. Stored vitamin A is released from the liver into the circulation as retinol bound to its specific transport protein, retinol-binding protein (RBP), which binds to the thyroid hormone transport protein, transthyretin (TTR); this complex delivers retinol (as well as the thyroid hormone) to a large number of vitamin A target tissues. The major physiologic mediator of retinol uptake by cells in many tissues is Stra6, a widely expressed multitransmembrane domain protein that functions as a cell-surface receptor for retinol bound to RBP.

In target tissues, retinol is either esterified into retinyl esters for storage or oxidized into retinoic acid for function. In the eye, 11-*cis*-retinal is formed.

Vitamin A Status in Neonates

Neonates begin life with low levels of vitamin A, in plasma, liver, and extrahepatic tissues, compared with those in adults. Normal plasma levels of retinol are 20-50 μg/dL in infants, and increase gradually as children become older. Median serum retinol values are 1.19 μmol/L in both boys and girls ages 4-8 yr; 1.4 and 1.33 μmol/L in boys and

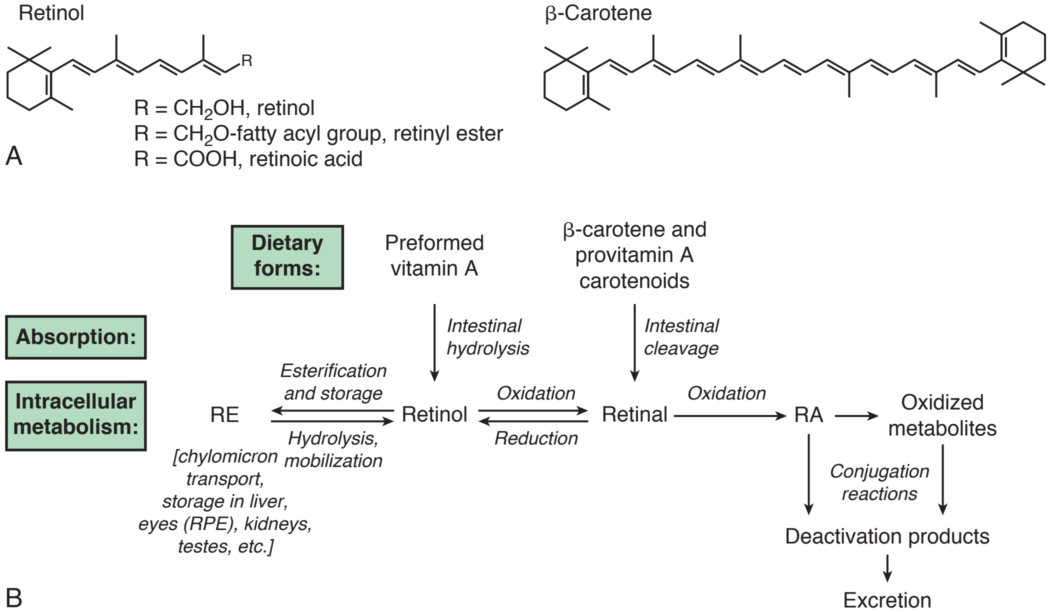

Figure 48-1 Vitamin A structures *(A)* and overview of vitamin A metabolism *(B)*.

girls, respectively, ages 9-13 yr; and 1.71 and 1.57 μmol/L in boys and girls, respectively, ages 14-18 yr (for conversion, 1 μmol/L = 28.6 μg/dL). Values of 1.96 and 1.85 μmol/L are found in 19-30 yr old adult men and women, respectively.

Retinol levels are even lower in neonates in developing countries where vitamin A intakes may be low and vitamin A deficiency is a common and significant nutritional problem. Lower vitamin A stores and plasma retinol concentrations are seen in low birthweight infants and in preterm newborns. Malnutrition, particularly protein nutrition, can cause vitamin A deficiency because of the impaired synthesis of RBP.

Inflammation as a Cause of Low Plasma Retinol

Inflammation is a cause of reduced levels of plasma retinol as a result of reduced synthesis of RBP and TTR. This condition may mimic a lack of vitamin A, but will not be corrected by supplementation. In U.S. adults, those with moderately elevated levels of C-reactive protein, indicative of mild inflammation, had lower average plasma retinol levels. The extent to which inflammation is a factor in low plasma retinol in children is uncertain but it is likely to be significant in acute infectious diseases such as measles, and possibly in chronic inflammatory conditions such as cystic fibrosis.

FUNCTIONS OF VITAMIN A AND MECHANISMS OF ACTION

Except for its role in vision, the pleiotropic actions of this micronutrient include many systemic functions that are mediated at the gene level by all-*trans*-retinoic acid (RA), which is a ligand for specific nuclear transcription factors, the retinoid receptors: RARs and RXRs. When an RAR is activated by the presence of RA, it combines with an RXR, and the resulting heterodimer binds to specific DNA sequences present in retinoid responsive genes (RAREs and RXREs, respectively) and therefore induce or repress the expression of a large number of genes. In this manner, vitamin A, via its active form, RA, regulates many genes that are involved in the fundamental biologic activities of cells, such as cell division, cell death, and cell differentiation. The term *retinoids* includes both natural and synthetic compounds with vitamin A activity and is most often used in the context of vitamin A action at the gene level. A large number of synthetic retinoids have been produced and some have gained clinical acceptance, such as in the treatment of skin disorders and certain cancers.

Retinoic acid is among the most important signaling molecules in vertebrate ontogenesis. It affects many physiologic processes, including reproduction, growth, embryonic and fetal development, and bone development, in addition to respiratory, gastrointestinal, hematopoietic, and immune functions. The role of vitamin A in immune function and host defense is particularly important in developing countries, where vitamin A supplementation or therapy reduces the morbidity and mortality rates of various diseases, such as measles (see Chapter 246).

Vitamin A plays a critical nongenomic role in vision. The human retina has 2 distinct photoreceptor systems: the rods, containing rhodopsin, which can detect low-intensity light, and the cones, containing iodopsin, which can detect different colors. The aldehyde form of vitamin A, retinal, is the prosthetic group on both visual proteins. The mechanism of vitamin A action in vision is based on the ability of the vitamin A molecule to photoisomerize (change shape when exposed to light). Thus, in the dark, low-intensity light isomerizes the rhodopsin prosthetic group, 11-*cis* retinal, to all-*trans*-retinal, generating an electrical signal that is transmitted via the optic nerve to the brain and results in visual sensation.

VITAMIN A DEFICIENCY

If the growing child has a well-balanced diet and obtains vitamin A from foods that are rich in vitamin A or provitamin-A (Table 48-1), the risk of vitamin A deficiency is small. However, even subclinical vitamin A deficiency can have serious consequences.

Deficiency states in developed countries are rare, except in some impoverished populations (see Chapter 46) or after mistakes in food preparation or with fad diets, but they are common in many developing countries and are often associated with global malnutrition (see Chapter 46). In the clinical setting, vitamin deficiencies can also occur as complications in children with various chronic disorders or diseases. Information obtained in the medical history related to dietary habits can be important in identifying the possibility of such nutritional problems. Except for vitamin A, toxicity from excess intake of vitamins is rare. Table 48-1 summarizes the food sources, functions, and deficiency and excess symptoms of the vitamins.

Clinical Manifestations of Vitamin A Deficiency

The most obvious symptoms of vitamin A deficiency are associated with the requirement of this vitamin for the maintenance of epithelial functions. In the intestines, a normal mucus-secreting epithelium (normal goblet cell function) is an effective barrier against pathogens that can cause diarrhea. Similarly, in the respiratory tract, a mucus-secreting epithelium is essential for the disposal of inhaled pathogens and toxicants. Characteristic changes as a result of vitamin A deficiency in the epithelia include a proliferation of basal cells, hyperkeratosis, and

Table 48-1 Vitamin A Characteristics

NAMES AND SYNONYMS	CHARACTERISTICS	BIOCHEMICAL ACTION	EFFECTS OF DEFICIENCY	EFFECTS OF EXCESS	SOURCES
Retinol (vitamin A_1); 1 μg retinol = 3.3 IU vitamin A = 1 RAE Provitamins A: the plant pigments α-, β-, and γ-carotenes and cryptoxanthin have partial retinol activity: 12 μg β-carotene, or 24 μg other provitamin A carotenoids = 1 μg retinol	Fat-soluble; heat-stable; destroyed by oxidation, drying Bile necessary for absorption Stored in liver Protected by vitamin E	In vision, as retinal, for synthesis of the visual pigments rhodopsin and iodopsin In growth, reproduction, embryonic and fetal development, bone growth, immune and epithelial functions, via retinoic acid as a ligand for specific nuclear transcription factors, regulating genes involved in many fundamental cellular processes	Nyctalopia Photophobia, xerophthalmia, Bitot spots, conjunctivitis, keratomalacia leading to blindness Faulty epiphyseal bone formation Defective tooth enamel Keratinization of mucous membranes and skin Retarded growth Impaired resistance to infection, anemia, reproductive failure, fetal abnormalities	Anorexia, slow growth, drying and cracking of skin, enlargement of liver and spleen, swelling and pain of long bones, bone fragility, increased intracranial pressure, alopecia, carotenemia Fetal abnormalities	Liver, fish liver oils Dairy products, except skim milk Egg yolk, fortified margarine, fortified skim milk Carotenoids from plants: green vegetables, yellow fruits, and vegetables

RAE, retinol activity equivalent.

formation of stratified cornified squamous epithelium. Squamous metaplasia of the renal pelves, ureters, vaginal epithelium, and the pancreatic and salivary ducts can lead to increased infections in these areas. In the urinary bladder, loss of epithelial integrity can result in pyuria and hematuria. Epithelial changes in the skin caused by vitamin A deficiency are manifested as dry, scaly, hyperkeratotic patches, commonly on the arms, legs, shoulders, and buttocks. The combination of defective epithelial barriers to infection, low immune response, and lowered response to inflammatory stress, all because of insufficient vitamin A, can cause poor growth and serious health problems in children.

The most characteristic and specific signs of vitamin A deficiency are eye lesions, but they may be manifest rather late in the progression of vitamin A deficiency. Lesions caused by vitamin A deficiency develop insidiously and rarely occur before 2 yr of age. An early symptom is delayed adaptation to the dark, a result of reduced resynthesis of rhodopsin; later, when vitamin A deficiency is more advanced, it leads to **night blindness** as a consequence of the absence of retinal in the visual pigment, rhodopsin, of the retina. Photophobia is a common symptom. The pigment epithelium, the structural element of the retina, keratinizes. When the pigment epithelium degenerates, the rods and cones have no support and eventually break down, resulting in blindness.

As vitamin A deficiency progresses, the corneal and conjunctival epithelial tissues of the eye become severely altered; this change results from a lack of sufficient RA for normal epithelial cell morphology and function. The cornea protects the eye from the environment and is also important in light refraction. In early vitamin A deficiency, the cornea keratinizes, becomes opaque, is susceptible to infection, and forms dry, scaly layers of cells **(xerophthalmia).** The conjunctiva keratinizes and develops plaques (**Bitot spots** [Fig. 48-2]). In later stages, infection occurs, lymphocytes infiltrate, and the cornea becomes wrinkled; it degenerates irreversibly (keratomalacia and corneal ulceration), resulting in blindness. Advanced xerophthalmia (Fig. 48-3) and xerophthalmia with permanent damage to the eye (Fig. 48-4) may develop if untreated. These eye lesions are primarily diseases of the young and are a major cause of blindness in developing countries. Although rates of xerophthalmia have fallen, the number of affected children is still too high.

Other clinical signs of vitamin A deficiency include poor overall growth, diarrhea, susceptibility to infections, anemia, apathy, mental retardation, and increased intracranial pressure, with wide separation of the cranial bones at the sutures. There may be vision problems as a consequence of bone overgrowth causing pressure on the optic nerve.

Malnutrition, particularly protein deficiency, can cause vitamin A deficiency by the impaired synthesis of retinol transport protein. In developing countries, subclinical or clinical zinc deficiency can increase the risk of vitamin A deficiency. There is also some evidence of marginal zinc intakes in children in the United States.

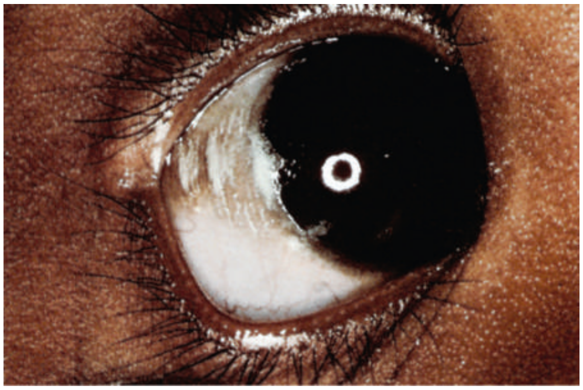

Figure 48-2 Bitot spots with hyperpigmentation seen in a 10 mo old Indonesian boy. *(From Oomen HAPC: Vitamin A deficiency, xerophthalmia and blindness,* Nutr Rev *6:161–166, 1974.)*

Diagnosis

Dark adaptation tests can be used to assess early-stage vitamin A deficiency. Although Bitot spots develop relatively early, those related to active vitamin A deficiency are usually confined to preschool-age children. Xerophthalmia is a very characteristic lesion of vitamin A deficiency. Caution must be exercised to exclude other, similar eye abnormalities from those associated with vitamin A deficiency. There are 3 useful indicators for detecting marginal vitamin A status, although they are mostly limited to research settings: conjunctival impression cytology, relative dose response, and modified relative dose response. A diet history can also be useful in suggesting or ruling out low intake as a cause. There is a relatively high prevalence of marginal vitamin A status among pregnant and lactating women. The plasma retinol level is not an accurate indicator of vitamin A status unless the deficiency is severe and liver stores are depleted, in which case low plasma retinol is likely to be evident. In children, plasma retinol values of <0.35 µmol/L are considered to be very deficient, 0.35-0.7 µmol/L are considered to be deficient, 0.7-1.05 µmol/L are considered to be marginal, and >1.05 µmol/L are considered to be adequate. It has long been thought that the liver vitamin A concentration must be 20 µg/g or higher to support a normal rate of secretion of retinol-RBP into plasma.

Epidemiology and Public Health Issues

Vitamin A deficiency and xerophthalmia still occur throughout much of the developing world and are linked to undernourishment and complicated by illness. Programs to provide periodic large doses of vitamin A have been instituted in many low-income countries in which vitamin

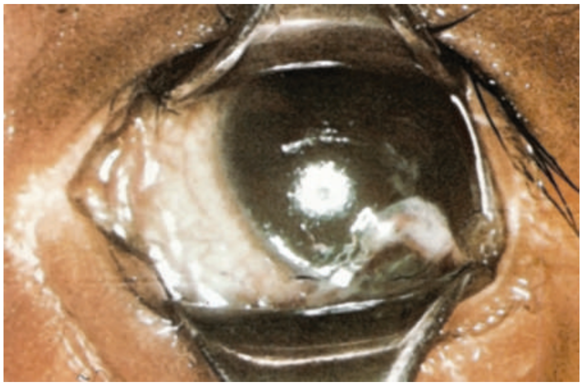

Figure 48-3 Advanced xerophthalmia with an opaque, dull cornea and some damage to the iris in a 1 yr old boy. *(From Oomen HAPC: Vitamin A deficiency, xerophthalmia and blindness,* Nutr Rev *6:161–166, 1974.)*

Table 48-2 Dietary Reference Intakes for Vitamin A in Children

AGE RANGE	RECOMMENDED DIETARY ALLOWANCE (RDA) (μg retinol equivalents per day)	UPPER LEVEL (UL) (μg retinol equivalents per day)	COMMENTS
0-6 mo	400	600	The recommended intake for infants is an adequate intake, based on the amount of vitamin A normally present in breast milk
7-12 mo	500	600	
1-3 yr	300	600	The UL applies only to preformed vitamin A (retinol).
4-8 yr	400	900	
9-13 yr	600	1,700	
14-18 yr	900 male; 700 female	2,800	

A deficiency is still a public health problem. Vitamin A supplementation is considered part of the strategy of the World Health Organization's Millennium Development Goals to reduce <5 yr mortality. Other strategies being tested include improving the content of β-carotene in staple foods through plant breeding (biofortification).

Dietary Reference Intakes for the Healthy Population

Table 48-2 summarizes the dietary reference intakes for infants and children. Dietary reference intake values include the estimated average requirement, which is the mean biologic requirement for the nutrient in the population; the recommended dietary allowance (RDA), which is set to cover the needs of >97% of the population (thus the needs of many people are more than covered by the RDA); and the upper level (UL), an intake level above which risk of adverse effects may increase; the UL pertains only to chronic consumption of preformed vitamin A. The RDA is expressed as retinol activity equivalents (RAEs; 1 RAE = 1 μg all-*trans*-retinol; equivalents for provitamin-A in foods = 12 μg β-carotene, 24 μg α-carotene, or 24 μg β-cryptoxanthin). From infancy to age 18 yr, the RDA increases as a consequence of increased body size, becoming higher for boys than girls during adolescence. During pregnancy, the RDA is 750-770 μg, and during lactation, the RDA is increased to 1,200-1,300 μg to ensure sufficient vitamin A content during breastfeeding.

It is noteworthy that, especially for young children, the UL is not far above the RDA, differing by only 2-fold in some age groups. This suggests that for children whose diet is good, care should be taken not to overuse dietary supplements containing preformed vitamin A and/or to avoid excessive consumption of foods that are rich in vitamin A, such as liver.

Vitamin A for Treatment of Deficiency

The safety and efficacy of vitamin A supplementation depend on the patient's state of health and the regimens of other treatments. A daily supplement of 1,500 μg of vitamin A is sufficient for treating latent vitamin A deficiency, after which intake an at RDA level should be the goal. In children without overt vitamin A deficiency, morbidity and mortality rates from viral infections, such as measles, have been reduced by administration of weekly doses equivalent to the RDA level of vitamin A, or higher doses of 30-60 mg of retinol (100,000-200,000 IU) given once or twice, under careful monitoring to avoid toxicity associated with excess vitamin A. Xerophthalmia is treated by giving 1,500 μg/kg body weight orally for 5 days followed by intramuscular injection of 7,500 μg of vitamin A in oil, until recovery.

Vitamin A is also used in preterm infants for improvement of respiratory function and prevention of the development of chronic lung disease. An analysis of 9 randomized controlled trials of vitamin A found that vitamin A appears to be beneficial in reducing death or oxygen requirement with no differences in neurodevelopmental outcomes.

HYPERVITAMINOSIS A

Chronic hypervitaminosis A results from excessive ingestion of preformed vitamin A (retinol or retinyl ester), generally for several weeks or months. The cause is often excessive use of vitamin A–containing supplements, or food faddism resulting in excessive intakes of organ meats. Toxicity can be induced in adults and children with chronic daily intakes of 15,000 μg and 6,000 μg, respectively. As there is no antidote for hypervitaminosis A, the prevention of this condition is most important. Symptoms may subside rapidly on withdrawal of the vitamin, but the rate of improvement depends on the amount of vitamin A that has built up in tissues. In extreme cases, hypervitaminosis A can be fatal. Signs of subacute or chronic toxicity can include headache; vomiting; anorexia; dry, itchy desquamating skin; seborrheic cutaneous lesions; fissuring at the corners of the mouth; alopecia and/or coarsening of the hair; bone abnormalities; swelling of the bones; enlargement of the liver and spleen; diplopia; increased intracranial pressure; irritability; stupor; limited motion; and dryness of the mucous membranes; desquamation of the palms and the soles of the feet. Radiographs may show hyperostosis affecting several long bones, especially in the middle of the shafts (Fig. 48-5). Serum levels of vitamin

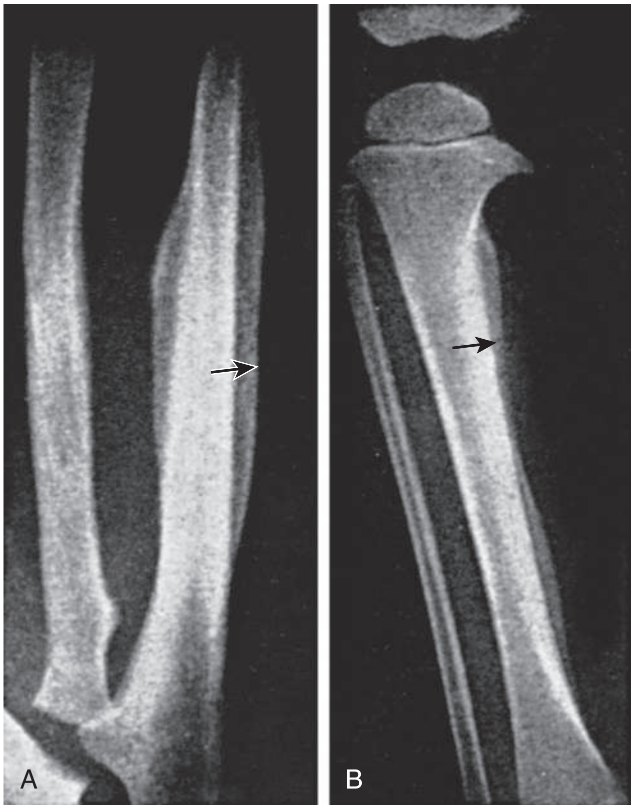

Figure 48-5 Hyperostosis of the ulna and tibia in an infant 21 mo of age, resulting from vitamin A positioning. *A,* Long, wavy cortical hyperostosis of the ulna (*arrow*). *B,* Long, wavy cortical hyperostosis of the right tibia (*arrow*), with a striking absence of metaphyseal changes. *(From Caffey J:* Pediatric x-ray diagnosis, *ed 5, Chicago, 1967, Year Book, p. 994.)*

A are elevated, mostly as retinyl ester contained in lipoproteins, which may contribute to membrane damage and symptoms, including release of liver enzymes into plasma. Hypercalcemia and/or liver cirrhosis may be present. Hypervitaminosis A is distinct from cortical hyperostosis (see Chapter 700).

In young children, toxicity is associated with vomiting and bulging fontanels. An affected child has anorexia, pruritus, and a lack of weight gain. Acute hypervitaminosis A, such as after consumption of a single large (30-60 mg dose) of vitamin A may include nausea, vomiting, and drowsiness; less-common symptoms include diplopia, papilledema, cranial nerve palsies, and other symptoms suggesting **pseudotumor cerebri.**

A syndrome of **severe congenital malformations** may occur in infants of mothers who have consumed therapeutic doses (0.5-1.5 mg/kg) of oral 13-*cis*-retinoic acid (e.g., Accutane), generally taken for the treatment of acne or cancer, during the 1st trimester of pregnancy. These malformations result in a high incidence (>20%) of spontaneous abortions and birth defects including characteristic craniofacial abnormalities. The U.S. Food and Drug Administration has increased the stringency of prescription of such drugs in women of childbearing age to attempt to reduce these birth defects.

Excessive intake of carotenoids is not associated with toxicity but can cause yellow coloration of the skin (carotenodermia) and serum (carotenemia) that disappears when intake is reduced. Children with liver disease, diabetes mellitus, or hypothyroidism are more susceptible. Food faddism including an excessive consumption of carotene-rich foods may be a cause of this condition.

Chapter **49**

Vitamin B Complex Deficiencies and Excess

H.P.S. Sachdev and Dheeraj Shah

Vitamin B complex includes a number of water-soluble nutrients, including thiamine (B_1), riboflavin (B_2), niacin (B_3), pyridoxine (B_6), folate, cobalamin (B_{12}), biotin, and pantothenic acid. Choline and inositol are also considered part of the B complex and are important for normal body functions, but specific deficiency syndromes have not been attributed to a lack of these factors in the diet.

B-complex vitamins serve as coenzymes in many metabolic pathways that are functionally closely related. Consequently, a lack of one of the vitamins has the potential to interrupt a chain of chemical processes, including reactions that are dependent on other vitamins, and ultimately can produce diverse clinical manifestations. Because diets deficient in any one of the B-complex vitamins are often poor sources of other B vitamins, manifestations of several vitamin B deficiencies usually can be observed in the same person. It is therefore a general practice in a patient who has evidence of deficiency of a specific B vitamin to treat with the entire B-complex group of vitamins.

49.1 Thiamine (Vitamin B_1)

H.P.S. Sachdev and Dheeraj Shah

Thiamine diphosphate, the active form of thiamine, serves as a cofactor for several enzymes involved in carbohydrate catabolism such as pyruvate dehydrogenase, transketolase, and α-ketoglutarate. These enzymes also play a role in the hexose monophosphate shunt that generates nicotinamide adenine dinucleotide phosphate (NADP) and pentose for nucleic acid synthesis. Thiamine is also required for the synthesis of acetylcholine and γ-aminobutyric acid, which have important roles in nerve conduction. Thiamine is absorbed efficiently in the gastrointestinal (GI) tract, and may be deficient in persons with GI or liver disease. The requirement of thiamine is increased when carbohydrates are taken in large amounts and during periods of increased metabolism, such as fever, muscular activity, hyperthyroidism, pregnancy, and lactation. Alcohol affects various aspects of thiamine transport and uptake, contributing to the deficiency in alcoholics.

Pork (especially lean), fish, and poultry are good nonvegetarian **dietary sources** of thiamine. Main sources of thiamine for vegetarians are rice, oat, wheat, and legumes. Most ready-to-eat breakfast cereals are enriched with thiamine. Thiamine is water soluble and heat labile; most of the vitamin is lost when the rice is repeatedly washed and the cooking water is discarded. The breast milk of a well-nourished mother provides adequate thiamine; breastfed infants of thiamine-deficient mothers are at risk for deficiency. Thiamine antagonists (coffee, tea) and thiaminases (fermented fish) may contribute to thiamine deficiency. Most infants and older children consuming a balanced diet obtain an adequate intake of thiamine from food and do not require supplements.

DEFICIENCY

Deficiency of thiamine is associated with severely malnourished states, including malignancy and following surgery. The disorder (or spectrum of disorders) is classically associated with a diet consisting largely of polished rice (oriental beriberi); it can also arise if highly refined wheat flour forms a major part of the diet, in alcoholics, and in food faddists (occidental beriberi). Thiamine deficiency has often been reported from inhabitants of refugee camps consuming the polished rice–based monotonous diets. Low thiamine concentrations are also noted during critical illnesses.

Thiamine-responsive megaloblastic anemia (TRMA) syndrome is a rare autosomal recessive disorder characterized by megaloblastic anemia, diabetes mellitus, and sensorineural hearing loss, responding in varying degrees to thiamine treatment. The syndrome occurs because of mutations in the *SLC19A2* gene, encoding a thiamine transporter protein, leading to abnormal thiamine transportation and cellular vitamin deficiency. Thiamine and related vitamins may improve the outcome in children with Leigh encephalomyelopathy and type 1 diabetes mellitus.

Clinical Manifestations

Thiamine deficiency can develop within 2-3 mo of a deficient intake. Early symptoms of thiamine deficiency are nonspecific, such as fatigue, apathy, irritability, depression, drowsiness, poor mental concentration, anorexia, nausea, and abdominal discomfort. As the condition progresses, more-specific manifestations of **beriberi,** such as peripheral neuritis (manifesting as tingling, burning, paresthesias of the toes and feet), decreased deep tendon reflexes, loss of vibration sense, tenderness and cramping of the leg muscles, heart failure, and psychological disturbances, develop. Patients can have ptosis of the eyelids and atrophy of the optic nerve. Hoarseness or aphonia caused by paralysis of the laryngeal nerve is a characteristic sign. Muscle atrophy and tenderness of the nerve trunks are followed by ataxia, loss of coordination, and loss of deep sensation. Later signs include increased intracranial pressure, meningismus, and coma. The clinical picture of thiamine deficiency is usually divided into a dry (neuritic) type and a wet (cardiac) type. The disease is wet or dry depending on the amount of fluid that accumulates in the body as a result of factors such as cardiac and renal dysfunction, even though the exact cause for this edema is unknown. Many cases of thiamine deficiency show a mixture of both features and are more properly termed *thiamine deficiency with cardiopathy and peripheral neuropathy.*

The classic clinical triad of **Wernicke encephalopathy** (mental status changes, ocular signs, ataxia) is rarely reported in infants and

young children with severe deficiency secondary to malignancies or feeding of defective formula. An epidemic of life-threatening thiamine deficiency was seen in infants fed a defective soy-based formula that had undetectable thiamine levels. Manifestations included emesis, lethargy, restlessness, ophthalmoplegia, abdominal distention, developmental delay, failure to thrive, lactic acidosis, nystagmus, diarrhea, apnea, seizures, and auditory neuropathy.

Death from thiamine deficiency usually is secondary to cardiac involvement. The initial signs are cyanosis and dyspnea, but tachycardia, enlargement of the liver, loss of consciousness, and convulsions can develop rapidly. The heart, especially the right side, is enlarged. The electrocardiogram shows an increased Q-T interval, inverted T waves, and low voltage. These changes, as well as the cardiomegaly, rapidly revert to normal with treatment, but without prompt treatment, cardiac failure can develop rapidly and result in death. In fatal cases of beriberi, lesions are principally located in the heart, peripheral nerves, subcutaneous tissue, and serous cavities. The heart is dilated, and fatty degeneration of the myocardium is common. Generalized edema or edema of the legs, serous effusions, and venous engorgement are often present. Degeneration of myelin and axon cylinders of the peripheral nerves, with wallerian degeneration beginning in the distal locations, is also common, particularly in the lower extremities. Lesions in the brain include vascular dilation and hemorrhage.

Diagnosis

The diagnosis is often suspected on the basis of clinical setting and compatible symptoms. A high index of suspicion in children presenting with unexplained cardiac failure may sometimes be lifesaving. Objective biochemical tests of thiamine status include measurement of erythrocyte transketolase activity and the thiamine pyrophosphate effect. The biochemical diagnostic criteria of thiamine deficiency consist of low erythrocyte transketolase activity and high thiamine pyrophosphate effect (normal range: 0-14%). Urinary excretion of thiamine or its metabolites (thiazole or pyrimidine) after an oral loading dose of thiamine may also be measured to help identify the deficiency state. MRI changes of thiamine deficiency in infants are characterized by bilateral symmetric hyperintensities of the basal ganglia and frontal lobe, in addition to the lesions in the mammillary bodies, periaqueductal region, and thalami described in adults.

Prevention

A maternal diet containing sufficient amounts of thiamine prevents thiamine deficiency in breastfed infants, and infant formulas marketed in all developed countries provide recommended levels of intake. During complementary feeding, adequate thiamine intake can be achieved with a varied diet that includes meat and enriched or whole-grain cereals. When the staple cereal is polished rice, special efforts need to be made to include legumes and/or nuts in the ration. Thiamine and other vitamins can be retained in rice by **parboiling**, a process of steaming the rice in the husk before milling. Improvement in cooking techniques, such as not discarding the water used for cooking, minimal washing of grains, and reduction of cooking time helps to minimize the thiamine losses during the preparation of food. Thiamine supplementation should be ensured during total parenteral nutrition.

Treatment

In the absence of GI disturbances, oral administration of thiamine is effective. Children with cardiac failure, convulsions, or coma should be given 10 mg of thiamine intramuscularly or intravenously daily for the 1st wk. This treatment should then be followed by 3-5 mg of thiamine per day orally for at least 6 wk. The response is dramatic in infants and in those having predominantly cardiovascular manifestations, whereas the neurologic response is slow and often incomplete. Epilepsy, mental disability, and language and auditory problems of varying degree have been reported in survivors of severe infantile thiamine deficiency.

Patients with beriberi often have other B-complex vitamin deficiencies; therefore, all other B-complex vitamins should also be administered. Treatment of TRMA and other dependency states require higher dosages (100-200 mg/day). The anemia responds well to thiamine administration, and insulin for associated diabetes mellitus can also be discontinued in many cases of TRMA.

TOXICITY

There are no reports of adverse effects from consumption of excess thiamine by ingestion of food or supplements. A few isolated cases of pruritus and anaphylaxis have been reported in patients after parenteral administration of the vitamin.

Bibliography is available at Expert Consult.

49.2 Riboflavin (Vitamin B_2)

H.P.S. Sachdev and Dheeraj Shah

Riboflavin is part of the structure of the coenzymes flavin adenine dinucleotide (FAD) and flavin mononucleotide, which participate in oxidation-reduction reactions in numerous metabolic pathways and in energy production via the mitochondrial respiratory chain. Riboflavin is stable to heat, but is destroyed by light. Milk, eggs, organ meats, legumes, and mushrooms are rich **dietary sources** of riboflavin. Most commercial cereals, flours, and breads are enriched with riboflavin.

DEFICIENCY

The causes of riboflavin deficiency are mainly related to malnourished and malabsorptive states, including GI infections. Treatment with some drugs, such as probenecid, phenothiazine, or oral contraceptives, can also cause the deficiency. The side chain of the vitamin is photochemically destroyed during phototherapy for hyperbilirubinemia, as it is involved in the photosensitized oxidation of bilirubin to more polar excretable compounds. Isolated **complex II deficiency**, a rare mitochondrial disease manifesting in infancy and childhood, responds favorably to riboflavin supplementation and thus can be termed a dependency state. **Brown-Vialetto-Van Laere syndrome** (BVVLS), a rare neurologic disorder characterized by progressive neurologic deterioration, hypotonia, sensorineural hearing loss, and pontobulbar palsy responds to treatment with high doses of riboflavin. Mutations in genes coding for riboflavin transporter proteins have been identified in children with BVVLS.

Clinical Manifestations

Clinical features of riboflavin deficiency include cheilosis, glossitis, keratitis, conjunctivitis, photophobia, lacrimation, corneal vascularization, and seborrheic dermatitis. Cheilosis begins with pallor at the angles of the mouth and progresses to thinning and maceration of the epithelium, leading to fissures extending radially into the skin (Fig. 49-1). In glossitis, the tongue becomes smooth, with loss of papillary structure (Fig. 49-2). Normochromic, normocytic anemia may also be seen because of the impaired erythropoiesis. A low riboflavin content of the maternal diet has been linked to congenital heart defects, but the evidence is weak.

Diagnosis

Most often, the diagnosis is based on the clinical features of angular cheilosis in a malnourished child, which responds promptly to riboflavin supplementation. A functional test of riboflavin status is done by measuring the activity of erythrocyte glutathione reductase (EGR), with and without the addition of FAD. An EGR activity coefficient (ratio of EGR activity with added FAD to EGR activity without FAD) of >1.4 is used as an indicator of deficiency. Urinary excretion of riboflavin <30 µg/24 hr also suggests low intakes.

Prevention

Table 49-1 lists the recommended daily allowance of riboflavin for infants, children, and adolescents. Adequate consumption of milk, milk products, and eggs prevents riboflavin deficiency. Fortification of

Table 49-1 Water-Soluble Vitamins

NAMES AND SYNONYMS	BIOCHEMICAL ACTION	EFFECTS OF DEFICIENCY	TREATMENT OF DEFICIENCY	CAUSES OF DEFICIENCY	DIETARY SOURCES	RDA* BY AGE
Thiamine (vitamin B_1)	Coenzyme in carbohydrate metabolism Nucleic acid synthesis Neurotransmitter synthesis	Neurologic (dry beriberi): irritability, peripheral neuritis, muscle tenderness, ataxia Cardiac (wet beriberi): tachycardia, edema, cardiomegaly, cardiac failure	3-5 mg/day PO thiamine for 6 wk	Polished rice–based diets Malabsorptive states Severe malnutrition Malignancies Alcoholism	Meat, especially pork; fish; liver Rice (unmilled), wheat germ; enriched cereals; legumes	0-6 mo: 0.2 mg/day 7-12 mo: 0.3 mg/day 1-3 yr: 0.5 mg/day 4-8 yr: 0.6 mg/day 9-13 yr: 0.9 mg/day 14-18 yr: Girls: 1.0 mg/day Boys: 1.2 mg/day
Riboflavin (vitamin B_2)	Constituent of flavoprotein enzymes important in oxidation-reduction reactions: amino acid, fatty acid, and carbohydrate metabolism and cellular respiration	Glossitis, photophobia, lacrimation, corneal vascularization, poor growth, cheilosis	3-10 mg/day PO riboflavin	Severe malnutrition Malabsorptive states Prolonged treatment with phenothiazines, probenecid, or OCPs	Milk, milk products, eggs, fortified cereals, green vegetables	0-6 mo: 0.3 mg/day 7-12 mo: 0.4 mg/day 1-3 yr: 0.5 mg/day 4-8 yr: 0.6 mg/day 9-13 yr: 0.9 mg/day 14-18 yr: Girls: 1.0 mg/day Boys: 1.3 mg/day
Niacin (vitamin B_3)	Constituent of NAD and NADP, important in respiratory chain, fatty acid synthesis, cell differentiation, and DNA processing	Pellagra manifesting as diarrhea, symmetric scaly dermatitis in sun-exposed areas, and neurologic symptoms of disorientation and delirium	50-300 mg/day PO niacin	Predominantly maize-based diets Anorexia nervosa Carcinoid syndrome	Meat, fish, poultry Cereals, legumes, green vegetables	0-6 mo: 2 mg/day 7-12 mo: 4 mg/day 1-3 yr: 6 mg/day 4-8 yr: 8 mg/day 9-13 yr: 12 mg/day 14-18 yr: Girls: 14 mg/day Boys: 16 mg/day
Pyridoxine (vitamin B_6)	Constituent of coenzymes for amino acid and glycogen metabolism, heme synthesis, steroid action, neurotransmitter synthesis	Irritability, convulsions, hypochromic anemia Failure to thrive Oxaluria	5-25 mg/day PO for deficiency states 100 mg IM or IV for pyridoxine-dependent seizures	Prolonged treatment with INH, penicillamine, OCPs	Fortified ready-to-eat cereals, meat, fish, poultry, liver, bananas, rice, potatoes	0-6 mo: 0.1 mg/day 7-12 mo: 0.3 mg/day 1-3 yr: 0.5 mg/day 4-8 yr: 0.6 mg/day 9-13 yr: 1.0 mg/day 14-18 yr: Girls: 1.2 mg/day Boys: 1.3 mg/day

Continued

Table 49-1 Water-Soluble Vitamins—cont'd

NAMES AND SYNONYMS	BIOCHEMICAL ACTION	EFFECTS OF DEFICIENCY	TREATMENT OF DEFICIENCY	CAUSES OF DEFICIENCY	DIETARY SOURCES	RDA* BY AGE
Biotin	Cofactor for carboxylases, important in gluconeogenesis, fatty acid and amino acid metabolism	Scaly periorificial dermatitis, conjunctivitis, alopecia, lethargy, hypotonia, and withdrawn behavior	1-10 mg/day PO biotin	Consumption of raw eggs for prolonged periods Parenteral nutrition with infusates lacking biotin Valproate therapy	Liver, organ meats, fruits	0-6 mo: 5 µg/day 7-12 mo: 6 µg/day 1-3 yr: 8 µg/day 4-8 yr: 12 µg/day 9-13 yr: 20 µg/day 14-18 yr: 25 µg/day
Pantothenic acid (vitamin B_5)	Component of coenzyme A and acyl carrier protein involved in fatty acid metabolism	Experimentally produced deficiency in humans: irritability, fatigue, numbness, paresthesias (burning feet syndrome), muscle cramps		Isolated deficiency extremely rare in humans	Beef, organ meats, poultry, seafood, egg yolk Yeast, soybeans, mushrooms	0-6 mo: 1.7 mg/day 7-12 mo: 1.8 mg/day 1-3 yr: 2 mg/day 4-8 yr: 3 mg/day 9-13 yr: 4 mg/day 14-18 yr: 5 mg/day
Folic acid	Coenzymes in amino acid and nucleotide metabolism as an acceptor and donor of one-carbon units	Megaloblastic anemia Growth retardation, glossitis Neural tube defects in progeny	0.5-1 mg/day PO folic acid	Malnutrition Malabsorptive states Malignancies Hemolytic anemias Anticonvulsant therapy	Enriched cereals, beans, leafy vegetables, citrus fruits, papaya	0-6 mo: 65 µg/day 7-12 mo: 80 µg/day 1-3 yr: 150 µg/day 4-8 yr: 200 µg/day 9-13 yr: 300 µg/day 14-18 yr: 400 µg/day
Cobalamin (vitamin B_{12})	As deoxyadenosylcobalamin, acts as cofactor for lipid and carbohydrate metabolism As methylcobalamin, important for conversion of homocysteine to methionine and folic acid metabolism	Megaloblastic anemia, irritability, developmental delay, developmental regression, involuntary movements, hyperpigmentation	1,000 µg IM vitamin B_{12}	Vegan diets Malabsorptive states Crohn disease Intrinsic factor deficiency (pernicious anemia)	Organ meats, sea foods poultry, egg yolk, milk, fortified ready-to-eat cereals	0-6 mo: 0.4 µg/day 7-12 mo: 0.5 µg/day 1-3 yr: 0.9 µg/day 4-8 yr: 1.2 µg/day 9-13 yr: 1.8 µg/day 14-18 yr: 2.4 µg/day
Ascorbic acid (vitamin C)	Important for collagen synthesis, metabolism of cholesterol and neurotransmitters Antioxidant functions and nonheme iron absorption	Scurvy manifesting as irritability, tenderness and swelling of legs, bleeding gums, petechiae, ecchymoses, follicular hyperkeratosis, and poor wound healing	100-200 mg/day PO ascorbic acid for up to 3 mo	Predominantly milk-based (non–human milk) diets Severe malnutrition	Citrus fruits and fruit juices, peppers, berries, melons, tomatoes, cauliflower, leafy green vegetables	0-6 mo: 40 mg/day 7-12 mo: 50 mg/day 1-3 yr: 15 mg/day 4-8 yr: 25 mg/day 9-13 yr: 45 mg/day 14-18 yr: Girls: 65 mg/day Boys: 75 mg/day

*For healthy breastfed infants, the values represent adequate intakes, that is, the mean intake of apparently "normal" infants.
INH, isoniazid; NAD, nicotinamide adenine dinucleotide; NADP, nicotinamide adenine dinucleotide phosphate; OCP, oral contraceptive pill; RDA, recommended dietary allowance.

cereal products is helpful for those who follow vegan diets or who are consuming inadequate amounts of milk products for other reasons.

Treatment

Treatment includes oral administration of 3-10 mg/day of riboflavin, often as an ingredient of a vitamin B–complex mix. The child should also be given a well-balanced diet, including milk and milk products.

TOXICITY

No adverse effects associated with riboflavin intakes from food or supplements have been reported, and the upper safe limit for consumption has not been established. Although the photosensitizing property of this vitamin raises the possibility for some potential risks, limited absorption in high-intake situations precludes such concerns.

Bibliography is available at Expert Consult.

49.3 Niacin (Vitamin B_3)

H.P.S. Sachdev and Dheeraj Shah

Niacin (nicotinamide or nicotinic acid) forms part of 2 cofactors, nicotinamide adenine dinucleotide and NADP, which are important in several biologic reactions, including the respiratory chain, fatty acid

and steroid synthesis, cell differentiation, and DNA processing. Niacin is rapidly absorbed from the stomach and the intestines and can also be synthesized from tryptophan in the diet.

Major **dietary sources** of niacin are meat, fish, and poultry for non-vegetarians and cereals, legumes, and green leafy vegetables for vegetarians. Enriched and fortified cereal products and legumes also are major contributors to niacin intake. Milk and eggs contain little niacin but are good sources of tryptophan, which can be converted to nicotinamide adenine dinucleotide (60 mg tryptophan = 1 mg niacin).

DEFICIENCY

Pellagra, the classic niacin deficiency disease, occurs chiefly in populations where corn (maize), a poor source of tryptophan, is the major foodstuff. A severe dietary imbalance, such as in anorexia nervosa and in war or famine conditions, also can cause pellagra. Pellagra can also develop in conditions associated with disturbed tryptophan metabolism such as carcinoid syndrome and Hartnup disease.

Clinical Manifestations

The early symptoms of pellagra are vague: anorexia, lassitude, weakness, burning sensation, numbness, and dizziness. After a long period of deficiency, the classic triad of dermatitis, diarrhea, and dementia appears. **Dermatitis**, the most characteristic manifestation of pellagra, can develop suddenly or insidiously and may be initiated by irritants, including intense sunlight. The lesions first appear as symmetric areas of erythema on exposed surfaces, resembling sunburn, and might go unrecognized. The lesions are usually sharply demarcated from the surrounding healthy skin, and their distribution can change frequently. The lesions on the hands and feet often have the appearance of a glove or stocking (Fig. 49-3). Similar demarcations can also occur around the neck (Casal necklace) (Fig. 49-3). In some cases, vesicles and bullae develop (wet type). In others, there may be suppuration beneath the scaly, crusted epidermis; in still others, the swelling can disappear after a short time, followed by desquamation (Fig. 49-4). The healed parts of the skin might remain pigmented. The cutaneous lesions may be preceded by or accompanied by stomatitis, glossitis, vomiting, and/or diarrhea. Swelling and redness of the tip of the tongue and its lateral margins is often followed by intense redness, even ulceration, of the entire tongue and the papillae. Nervous symptoms include depression, disorientation, insomnia, and delirium.

The classic symptoms of pellagra usually are not well developed in infants and young children, but anorexia, irritability, anxiety, and apathy are common. Young patients might also have sore tongues and lips, and usually have dry and scaly skin. Diarrhea and constipation can alternate, and anemia can occur. Children who have pellagra often have evidence of other nutritional deficiency diseases.

Diagnosis

Because of lack of a good functional test to evaluate niacin status, the diagnosis of deficiency is usually made from the physical signs of glossitis, GI symptoms, and a symmetric dermatitis. Rapid clinical response to niacin is an important confirmatory test. A decrease in the concentration and/or a change in the proportion of the niacin metabolites N^1-methyl-nicotinamide and 2-pyridone in the urine provide biochemical evidence of deficiency and can be seen before the appearance of overt signs of deficiency. Histopathologic changes from the affected skin include dilated blood vessels without significant inflammatory infiltrates, ballooning of the keratinocytes, hyperkeratosis, and epidermal necrosis.

Prevention

Adequate intakes of niacin are easily met by consumption of a diet that consists of a variety of foods and includes meat, eggs, milk, and enriched or fortified cereal products. The dietary reference intake (DRI) is expressed in mg niacin equivalents (NE) in which 1 mg NE = 1 mg niacin or 60 mg tryptophan. An intake of 2 mg of niacin is considered adequate for infants 0-6 mo of age; and 4 mg is adequate for infants 7-12 mo of age. For older children, the recommended

Figure 49-3 Characteristic skin lesions of pellagra on hands and lesions on the neck (Casal necklace). *(Courtesy of Dr. J.D. MacLean, McGill Centre for Tropical Diseases, Montreal, Canada.)*

Figure 49-4 Clinical manifestations of niacin deficiency before *(A)* and after *(B)* therapy. *(From Weinsier RL, Morgan SL:* Fundamentals of clinical nutrition, *St. Louis, 1993, Mosby, p. 99.)*

intakes are 6 mg for 1-3 yr of age, 8 mg for 4-8 yr of age, 12 mg for 9-13 yr of age, and 14-16 mg for 14-18 yr of age.

Treatment

Children usually respond rapidly to treatment. A liberal and varied diet should be supplemented with 50-300 mg/day of niacin; in severe cases or in patients with poor intestinal absorption, 100 mg may be given intravenously. The diet should also be supplemented with other vitamins, especially other B-complex vitamins. Sun exposure should be avoided during the active phase of pellagra, and the skin lesions may be covered with soothing applications. Other coexisting nutrient deficiencies such as iron deficiency anemia should be treated. Even after successful treatment, the diet should continue to be monitored to prevent recurrence.

TOXICITY

There are no toxic effects associated with the intake of naturally occurring niacin in foods. Shortly after the ingestion of large doses of nicotinic acid taken as a supplement or a pharmacologic agent, a person often experiences a burning, tingling, and itching sensation as well as flushing on the face, arms, and chest. Large doses of niacin also can have nonspecific GI effects and can cause cholestatic jaundice or hepatotoxicity. Tolerable upper intake levels for children are approximately double the recommended dietary allowance.

Bibliography is available at Expert Consult.

49.4 Vitamin B_6 (Pyridoxine)

H.P.S. Sachdev and Dheeraj Shah

Vitamin B_6 includes a group of closely related compounds: pyridoxine, pyridoxal, pyridoxamine, and their phosphorylated derivatives. Pyridoxal 5′-phosphate (PLP) and, to a lesser extent, pyridoxamine phosphate function as coenzymes for many enzymes involved in amino acid metabolism, neurotransmitter synthesis, glycogen metabolism, and steroid action. If vitamin B_6 is lacking, glycine metabolism can lead to oxaluria. The major excretory product in the urine is 4-pyridoxic acid.

The vitamin B_6 content of human milk and infant formulas is adequate. Good **food sources** of the vitamin include fortified ready-to-eat cereals, meat, fish, poultry, liver, bananas, rice, and certain vegetables. Large losses of the vitamin can occur during high-temperature processing of foods or milling of cereals, whereas parboiling of rice prevents its loss.

DEFICIENCY

Because of the importance of vitamin B_6 in amino acid metabolism, high protein intakes can increase the requirement for the vitamin; the recommended daily allowances are sufficient to cover the expected range of protein intake in the population. The risk of deficiency is increased in persons taking medications that inhibit the activity of vitamin B_6 (isoniazid, penicillamine, corticosteroids, phenytoin, carbamazepine), in young women taking oral progesterone-estrogen contraceptives, and in patients receiving maintenance dialysis.

Clinical Manifestations

The deficiency symptoms seen in infants are listlessness, irritability, seizures, vomiting, and failure to thrive. Peripheral neuritis is a feature of deficiency in adults but is not usually seen in children. Electroencephalogram (EEG) abnormalities have been reported in infants as well as in young adult subjects in controlled depletion studies. Skin lesions include cheilosis, glossitis, and seborrheic dermatitis around the eyes, nose, and mouth. Microcytic anemia can occur in infants, but is not common. Oxaluria, oxalic acid bladder stones, hyperglycinemia, lymphopenia, decreased antibody formation, and infections also are associated with vitamin B_6 deficiency.

Several types of vitamin B_6 **dependence syndromes,** presumably resulting from errors in enzyme structure or function, respond to very large amounts of pyridoxine. These syndromes include pyridoxine-dependent epilepsy, a vitamin B_6–responsive anemia, xanthurenic aciduria, cystathioninuria, and homocystinuria (see Chapters 85, 456, and 601). Pyridoxine-dependent epilepsy involves mutations in the *ALDH7A1* gene causing deficiency of antiquitin, an enzyme involved in dehydrogenation of L-alpha-aminoadipic semialdehyde.

Diagnosis

The activity of the erythrocyte transaminases glutamic oxaloacetic transaminase and glutamic pyruvic transaminase is low in vitamin B_6 deficiency; tests measuring the activity of these enzymes before and after the addition of PLP may be useful as indicators of vitamin B_6 status. Abnormally high xanthurenic acid excretion after tryptophan ingestion also provides evidence of deficiency. Plasma PLP assays are being used more often, but factors other than deficiency can influence the results. Vitamin B_6 deficiency or dependence should be suspected in all infants with seizures. If more common causes of infantile seizures have been eliminated, 100 mg of pyridoxine can be injected, with EEG monitoring if possible. If the seizure stops, vitamin B_6 deficiency should be suspected. In older children, 100 mg of pyridoxine may be injected intramuscularly while the EEG is being recorded; a favorable response of the EEG suggests pyridoxine deficiency.

Prevention

Deficiency is unlikely in children consuming diets that meet their energy needs and contain a variety of foods. **Parboiling** of rice prevents the loss of vitamin B_6 from the grains. The DRIs for vitamin B_6 are 0.1 mg/day for infants up to 6 mo of age; 0.3 mg/day for ages 6 mo to 1 yr; 0.5 mg/day for ages 1-3 yr; 0.6 mg/day for ages 4-8 yr; 1.0 mg/day for ages 9-13 yr; and 1.2-1.3 mg/day for ages 14-18 yr. Infants whose mothers have received large doses of pyridoxine during pregnancy are at increased risk for seizures from pyridoxine dependence, and supplements during the 1st few weeks of life should be considered. Any child receiving a pyridoxine antagonist, such as isoniazid, should be carefully observed for neurologic manifestations; if these develop, vitamin B_6 should be administered or the dose of the antagonist should be decreased.

Treatment

Intramuscular or intravenous administration of 100 mg of pyridoxine is used to treat convulsions caused by vitamin B_6 deficiency. One dose should be sufficient if adequate dietary intake follows. For pyridoxine-dependent children, daily doses of 2-10 mg intramuscularly or 10-100 mg orally may be necessary.

TOXICITY

Adverse effects have not been associated with high intakes of vitamin B_6 from food sources. However, ataxia and sensory neuropathy have been reported with dosages as low as 100 mg/day in adults taking vitamin B_6 supplements for several months.

Bibliography is available at Expert Consult.

49.5 Biotin

H.P.S. Sachdev and Dheeraj Shah

Biotin functions as a cofactor for enzymes involved in carboxylation reactions within and outside mitochondria. These biotin-dependent carboxylases catalyze key reactions in gluconeogenesis, fatty acid metabolism, and amino acid catabolism.

There is limited information on the biotin content of foods; it is believed to be widely distributed, thus making a deficiency unlikely. Avidin found in raw egg whites acts as a biotin antagonist. Signs of biotin deficiency have been demonstrated in persons who consume large amounts of raw egg whites over long periods. Deficiency also has been described in infants and children receiving enteral and parenteral

nutrition formula that lack biotin. Treatment with valproic acid may result in a low biotinidase activity and/or biotin deficiency.

The clinical findings of biotin deficiency include scaly periorificial dermatitis, conjunctivitis, thinning of hair, and alopecia (Fig. 49-5). Central nervous system abnormalities seen with biotin deficiency are lethargy, hypotonia, seizures, ataxia, and withdrawn behavior. Biotin deficiency can be successfully treated using 1-10 mg of biotin orally daily. The adequate dietary intake values for biotin are 5 µg/day for ages 0-6 mo, 6 µg/day for ages 7-12 mo, 8 µg/day for ages 1-3 yr, 12 µg/day for ages 4-8 yr, 20 µg/day for ages 9-13 yr, and 25 µg/day for ages 14-18 yr. No toxic effects have been reported with very high doses.

Biotin responsive basal ganglia disease is a rare childhood neurologic disorder characterized by encephalopathy, seizures, and extrapyramidal manifestations. Chapter 85.6 describes conditions involving deficiencies in the enzymes holocarboxylase synthetase and biotinidase that respond to treatment with biotin.

Bibliography is available at Expert Consult.

49.6 Folate

H.P.S. Sachdev and Dheeraj Shah

Folate exists in a number of different chemical forms. Folic acid (pteroylglutamic acid) is the synthetic form used in fortified foods and supplements. Naturally occurring folates in foods retain the core chemical structure of pteroylglutamic acid but vary in their state of reduction, the single carbon moiety they bear, or the length of the glutamate chain. These polyglutamates are broken down and reduced in the small intestine to dihydro- and tetrahydrofolates, which are involved as coenzymes in amino acid and nucleotide metabolism as acceptors and donors of 1-carbon units. Folate is important for central nervous system development during embryogenesis.

Rice and cereals are rich **dietary sources** of folate, especially if enriched. Beans, leafy vegetables, and fruits such as oranges and papaya are good sources, too. The vitamin is readily absorbed from the small intestine and is broken down to monoglutamate derivatives by mucosal polyglutamate hydrolases. A high-affinity proton-coupled folate transporter (PCFT) seems to be essential for absorption of folate in intestine and in various cell types at low pH. The vitamin is also synthesized by the colonic bacteria, and the half-life of the vitamin is prolonged by enterohepatic recirculation.

DEFICIENCY

Because of its role in protein, DNA, and RNA synthesis, the risk of deficiency is increased during periods of rapid growth or increased cellular metabolism. Folate deficiency can result from poor nutrient content in diet, inadequate absorption (celiac disease, inflammatory bowel disease), increased requirement (sickle cell anemia, psoriasis, malignancies, periods of rapid growth as in infancy and adolescence), or inadequate utilization (long-term treatment with high-dose nonsteroidal antiinflammatory drugs; anticonvulsants such as phenytoin and phenobarbital; and methotrexate). Rare causes of deficiency are hereditary folate malabsorption, inborn errors of folate metabolism (methylene tetrahydrofolate reductase, methionine synthase reductase, and glutamate formiminotransferase deficiencies), and cerebral folate deficiency. A loss-of-function mutation in the gene coding for PCFT is the molecular basis for hereditary folate malabsorption. A high-affinity blocking autoantibody against the membrane-bound folate receptor in the choroid plexus preventing its transport across the blood–brain barrier is the likely cause of the infantile cerebral folate deficiency.

Clinical Manifestations

Folic acid deficiency results in megaloblastic anemia and hypersegmentation of neutrophils. Nonhematologic manifestations include glossitis, listlessness, and growth retardation not related to anemia. There is an association between low maternal folic acid status and neural tube defects, primarily spina bifida and anencephaly, and the role of periconceptional folic acid in their prevention is well established.

Hereditary folate malabsorption manifests at 1-3 mo of age with recurrent or chronic diarrhea, failure to thrive, oral ulcerations, neurologic deterioration, megaloblastic anemia, and opportunistic infections. Cerebral folate deficiency manifests at 4-6 mo of age with irritability, microcephaly, developmental delay, cerebellar ataxia, pyramidal tract signs, choreoathetosis, ballismus, seizures, and blindness as a result of optic atrophy. 5-Methyltetrahydrofolate levels are normal in serum and red blood cells (RBCs), but are markedly depressed in the cerebrospinal fluid.

Diagnosis

The diagnosis of folic acid deficiency anemia is made in the presence of macrocytosis along with low folate levels in serum and/or RBCs. Normal serum folic acid levels are 5-20 ng/mL; with deficiency, serum folic acid levels are <3 ng/mL. Levels of RBC folate are a better indicator of chronic deficiency. The normal RBC folate level is 150-600 ng/mL of packed cells. The bone marrow is hypercellular because of erythroid hyperplasia, and megaloblastic changes are prominent. Large, abnormal neutrophilic forms (giant metamyelocytes) with cytoplasmic vacuolation also are seen.

Cerebral folate deficiency is associated with low levels of 5-methyltetrahydrofolate in the cerebrospinal fluid and normal folate levels in the plasma and RBCs. Mutations in the PCFT gene are demonstrated in the hereditary folate malabsorption.

Prevention

Breastfed infants have better folate nutrition than non–breastfed infants throughout infancy. Consumption of folate-rich foods and food-fortification programs are important to ensure adequate intake in children and in women of childbearing age. The DRIs for folate are 65 µg of dietary folate equivalents (DFE) for infants 0-6 mo of age and 80 µg of DFE for infants between 6 and 12 mo of age. (1 DFE = 1 µg food folate = 0.6 µg of folate from fortified food or as a supplement consumed with food = 0.5 µg of a supplement taken on an empty stomach.) For older children, the DRIs are 150 µg of DFE for ages 1-3 yr; 200 µg of DFE for ages 4-8 yr; 300 µg of DFE for ages 9-13 yr; and 400 µg of DFE for ages 14-18 yr. All women desirous of becoming pregnant should consume 400-800 µg folic acid daily; the dose is 4 mg/day in those having delivered a child with neural tube defect. To be effective, supplementation should be started at least 1 mo before conception, and continued through the first 2-3 mo of pregnancy. There may be a marginal benefit of periconceptional folate supplementation in prevention of autistic spectrum disorders. Providing iron and folic acid tablets for prevention of anemia in children and pregnant women is a routine strategy in at-risk populations. Mandatory fortification of cereal flours with folic acid coupled with health-education programs has been associated with a substantial reduction in incidence of neural tube defects in many countries.

Treatment

When the diagnosis of folate deficiency is established, folic acid may be administered orally or parenterally at 0.5-1.0 mg/day. Folic acid therapy should be continued for 3-4 wk or until a definite hematologic response has occurred. Maintenance therapy with 0.2 mg of folate is adequate. Prolonged treatment with oral folinic acid is required in cerebral folate deficiency, and the response may be incomplete. Treatment of hereditary folate malabsorption may be possible with intramuscular folinic acid; some patients may respond to high-dose oral folinic acid therapy.

TOXICITY

No adverse effects have been associated with consumption of the amounts of folate normally found in fortified foods. Excessive intake of folate supplements might obscure and potentially delay the diagnosis of vitamin B_{12} deficiency. Massive doses given by injection have the potential to cause neurotoxicity.

Bibliography is available at Expert Consult.

49.7 Vitamin B_{12} (Cobalamin)

H.P.S. Sachdev and Dheeraj Shah

Vitamin B_{12}, in the form of deoxyadenosylcobalamin, functions as a cofactor for isomerization of methylmalonyl-CoA to succinyl-CoA, an essential reaction in lipid and carbohydrate metabolism. Methylcobalamin is another circulating form of vitamin B_{12}, and is essential for methyl group transfer during the conversion of homocysteine to methionine. This reaction also requires a folic acid cofactor and is important for protein and nucleic acid biosynthesis. Vitamin B_{12} is important for hematopoiesis, central nervous system myelination, and mental and psychomotor development.

Dietary sources of vitamin B_{12} are almost exclusively from animal foods. Organ meats, muscle meats, sea foods (mollusks, oysters, fish), poultry, and egg yolk are rich sources. Fortified ready-to-eat cereals and milk and their products are the important sources of the vitamin for vegetarians. Human milk is an adequate source for breastfeeding infants if the maternal serum B_{12} levels are adequate. The vitamin is absorbed from ileum at alkaline pH after binding with intrinsic factor. Enterohepatic circulation, direct absorption, and synthesis by intestinal bacteria are additional mechanisms helping to maintain the vitamin B_{12} nutriture.

DEFICIENCY

Vitamin B_{12} deficiency because of inadequate dietary intake occurs primarily in persons consuming strict vegetarian or vegan diets. Prevalence of vitamin B_{12} deficiency is high in predominantly vegetarian or lactovegetarian populations. Breastfeeding infants of B_{12}-deficient mothers are also at risk for significant deficiency. Malabsorption of B_{12} occurs in celiac disease, ileal resections, Crohn disease, *Helicobacter pylori* infection, and autoimmune atrophic gastritis (pernicious anemia). Use of proton pump inhibitors and/or histamine 2 receptor antagonists may increase the risk of deficiency. Hereditary intrinsic factor deficiency and Imerslund-Gräsbeck disease are inborn errors of metabolism leading to vitamin B_{12} malabsorption. Mutations in the hereditary intrinsic factor gene cause hereditary intrinsic factor deficiency, whereas mutations in any of the 2 subunits (cubilin and amnionless) of the intrinsic factor receptor cause Imerslund-Gräsbeck disease.

Clinical Manifestations

The hematologic manifestations of vitamin B_{12} deficiency are similar to manifestations of folate deficiency and are discussed in Chapter 454.2. Irritability, hypotonia, developmental delay, developmental regression, and involuntary movements are the common neurologic symptoms in infants and children, whereas sensory deficits, paresthesias, and peripheral neuritis are seen in adults. Hyperpigmentation of the knuckles (Fig. 49-6) and palms is another common observation with B_{12} deficiency in children. Maternal B_{12} deficiency may also be an independent risk factor for fetal neural tube defects.

Figure 49-6 Hyperpigmentation of knuckles in an infant with vitamin B_{12} deficiency and megaloblastic anemia.

Diagnosis

See Chapter 454.2.

Treatment

The hematologic symptoms respond promptly to parenteral administration of 250-1,000 µg vitamin B_{12}. Children with severe deficiency and those with neurologic symptoms need repeated doses; daily or alternate days in first week followed by weekly for the first 1-2 mo, and then monthly thereafter. Children having only hematologic presentation recover fully within 2-3 mo, whereas those with neurologic disease need at least 6 mo of therapy. Children with continuing malabsorptive state, and those having inborn errors of vitamin B_{12} malabsorption need lifelong treatment. Prolonged daily treatment with high dose (1,000-2,000 µg) oral vitamin B_{12} preparations has also been found to be equally effective in achieving hematologic and neurologic responses in the elderly, but the data are inadequate in children and young adults.

Prevention

The DRIs are 0.4 µg/day at age 0-6 mo, 0.5 µg/day at age 6-12 mo, 0.9 µg/day at age 1-3 yr, 1.2 µg/day at age 4-8 yr, 1.8 µg/day at age 9-13 yr, 2.4 µg/day at age 14-18 yr and in adults, 2.6 µg/day in pregnancy, and 2.8 µg/day in lactation. Pregnant and breastfeeding women should ensure an adequate consumption of animal products to prevent the deficiency in infants. Strict vegetarians, especially vegans, should ensure regular consumption of vitamin B_{12}. Food fortification with the vitamin helps to prevent deficiency in predominantly vegetarian populations.

Chapter 50

Vitamin C (Ascorbic Acid)

Dheeraj Shah and H.P.S. Sachdev

Vitamin C is important for synthesis of collagen at the level of hydroxylation of lysine and proline in precollagen. It is also involved in neurotransmitter metabolism (conversion of dopamine to norepinephrine and tryptophan to serotonin), cholesterol metabolism (conversion of cholesterol to steroid hormones and bile acids), and the biosynthesis of carnitine. Vitamin C functions to maintain the iron and copper atoms, cofactors of the metalloenzymes, in a reduced (active) state. Vitamin C is an important antioxidant (electron donor) in the aqueous milieu of the body. Vitamin C enhances nonheme iron absorption, the transfer of iron from transferrin to ferritin, and the formation of tetrahydrofolic acid and thus can affect the cellular and immunologic functions of the hematopoietic system.

DIETARY NEEDS AND SOURCES

Humans depend on dietary sources for vitamin C. An adequate intake is 40 mg for age 0-6 mo and 50 mg for age 6-12 mo. For older children, the recommended dietary allowance is 15 mg for age 1-3 yr, 25 mg for age 4-8 yr, 45 mg for age 9-13 yr, and 65-75 mg for age 14-18 yr. The recommended dietary allowances during pregnancy and lactation are 85 mg/day and 120 mg/day, respectively. The requirement for vitamin C is increased during infectious and diarrheal diseases. Children exposed to smoking or environmental tobacco smoke also require increased amounts of foods rich in vitamin C. The best food sources of vitamin C are citrus fruits and fruit juices, peppers, berries, melons, tomatoes, cauliflower, and green leafy vegetables. Vitamin C is easily destroyed by prolonged storage, overcooking, and processing of foods.

Absorption of vitamin C occurs in the upper small intestine by an active process or by simple diffusion when large amounts are ingested. Vitamin C is not stored in the body but is taken up by all tissues; the highest levels are found in the pituitary and adrenal glands. The brain ascorbate content in the fetus and neonate is manyfold higher than the content in the adult brain, a finding probably related to its function in neurotransmitter synthesis.

When a mother's intake of vitamin C during pregnancy and lactation is adequate, the newborn will have adequate tissue levels of vitamin C related to active placental transfer, subsequently maintained by the vitamin C in breast milk or commercial infant formulas. Breast milk contains sufficient vitamin C to prevent deficiency throughout infancy. Infants consuming pasteurized or boiled animal milk are at significant risk of developing deficiency if the other sources of vitamin C are also lacking in the diet. Neonates whose feeding has been delayed because of clinical condition can also suffer from ascorbic acid deficiency. For patients on total parenteral nutrition, a parenteral dose of 80 mg/day is recommended for full-term infants and a parenteral dose of 25 mg/kg/day is recommended for preterm infants. Children who choose a limited diet or those on fad diets are at risk for vitamin C deficiency.

DEFICIENCY

A deficiency of vitamin C results in the clinical presentation of **scurvy**, the oldest nutritional deficiency disease to be recognized. Children fed predominantly heat-treated (ultrahigh-temperature or pasteurized) milk or unfortified formulas and not receiving fruits and fruit juices are at significant risk for symptomatic disease. In scurvy, there is defective formation of connective tissues and collagen in skin, cartilage, dentine, bone, and blood vessels, leading to their fragility. In the long bones, osteoid is not deposited by osteoblasts, cortex is thin, and the trabeculae become brittle and fracture easily.

Clinical Features

The early manifestations are irritability, loss of appetite, low-grade fever, musculoskeletal pain, and tenderness in the legs. These signs and symptoms are followed by leg swelling—most marked at the knees and the ankles—and **pseudoparalysis**. The infant might lie with the hips and knees semiflexed and the feet rotated outward. Subperiosteal hemorrhages in the lower limb bones sometimes acutely increase the swelling and pain, and the condition might mimic acute osteomyelitis or arthritis. A "rosary" at the costochondral junctions and depression of the sternum are other typical features (Fig. 50-1). The angulation of scorbutic beads is usually sharper than the angulation of a rachitic rosary. Gum changes are seen in older children after teeth have erupted and are manifested as bluish purple, spongy swellings of the mucous membrane, especially over the upper incisors (Fig. 50-2). Anemia, a common finding in infants and young children with scurvy, is related to impaired iron absorption and coexistent hematopoietic nutrient deficiencies including iron, vitamin B_{12}, and folate. Hemorrhagic

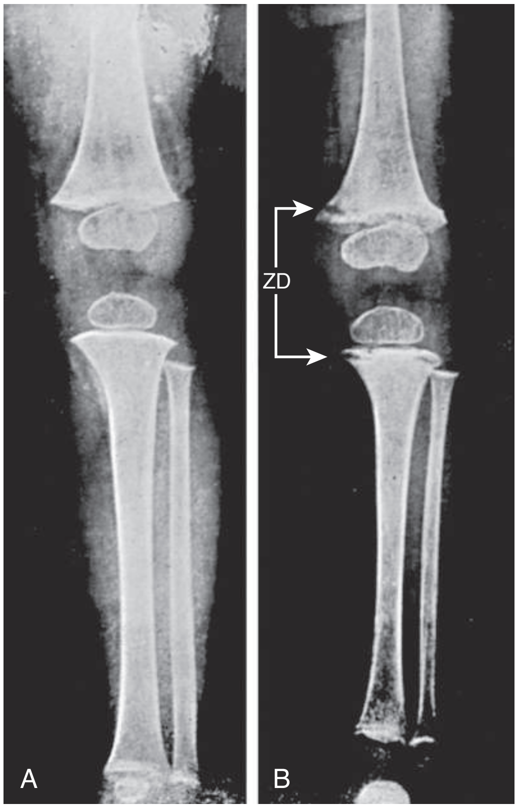

Figure 50-4 Radiographs of a leg. *A,* An early scurvy "white line" is visible on the ends of the shafts of the tibia and fibula; sclerotic rings (Wimberger sign) are shown around the epiphyses of the femur and tibia. *B,* More advanced scorbutic changes; zones of destruction (ZD) are evident in the femur and tibia. Pelkan spur is also seen at the cortical end.

manifestations of scurvy include petechiae, purpura, and ecchymoses at pressure points; epistaxis; gum bleeding; and the characteristic perifollicular hemorrhages (Fig. 50-3). Other manifestations are poor wound and fracture healing, hyperkeratosis of hair follicles, arthralgia, and muscle weakness.

Laboratory Findings and Diagnosis

The diagnosis of vitamin C deficiency is usually based on the characteristic clinical picture, the radiographic appearance of the long bones, and a history of poor vitamin C intake. The typical **radiographic changes** occur at the distal ends of the long bones and are particularly common at the knees. The shafts of the long bones have a ground-glass appearance because of trabecular atrophy. The cortex is thin and dense, giving the appearance of *pencil outlining* of the diaphysis and epiphysis. The *white line of Fränkel,* an irregular but thickened white line at the metaphysis, represents the zone of well-calcified cartilage. The epiphyseal centers of ossification also have a ground-glass appearance and are surrounded by a sclerotic ring (Fig. 50-4). The more specific but late radiologic feature of scurvy is a zone of rarefaction under the white line at the metaphysis. This zone of rarefaction *(Trümmerfeld zone),* a linear break in the bone that is proximal and parallel to the white line, represents area of debris of broken-down bone trabeculae and connective tissue. A *Pelkan spur* is a lateral prolongation of the white line and may be present at cortical ends. Epiphyseal separation can occur along the line of destruction, with either linear displacement or compression of the epiphysis against the shaft (Fig. 50-5). Subperiosteal hemorrhages are not visible using plain radiographs during the active phase of scurvy. However, during healing the elevated periosteum becomes calcified and radiopaque (Fig. 50-5), sometimes giving a dumbbell or club shape to the affected bone. MRI can demonstrate acute as well as healing subperiosteal hematomas along with periostitis, metaphyseal changes, and heterogeneous bone marrow signal intensity, even in absence of changes in plain radiographs. Gelatinous transformation of bone marrow, on aspiration, has been reported in children where the procedure was done on suspicion of a malignancy.

Biochemical tests are not very useful in the diagnosis of scurvy, because they do not reflect the tissue status. A plasma ascorbate concentration of <0.2 mg/dL usually is considered deficient. Leukocyte concentration of vitamin C is a better indicator of body stores, but this measurement is technically more difficult to perform. Leukocyte concentrations of $\leq 10\ \mu g/10^8$ white blood cells are considered deficient and indicate latent scurvy, even in the absence of clinical signs of deficiency. Saturation of the tissues with vitamin C can be estimated from the urinary excretion of the vitamin after a test dose of ascorbic acid. In healthy children, 80% of the test dose appears in the urine within 3-5 hr after parenteral administration. Generalized nonspecific aminoaciduria is common in scurvy, whereas plasma amino acid levels remain normal.

Differential Diagnosis

Scurvy is often misdiagnosed as arthritis, osteomyelitis, nonaccidental trauma (child abuse), or acrodynia. The early irritability and bone pain are sometimes attributed to nonspecific pains or other nutritional deficiencies. Copper deficiency results in a radiographic picture very

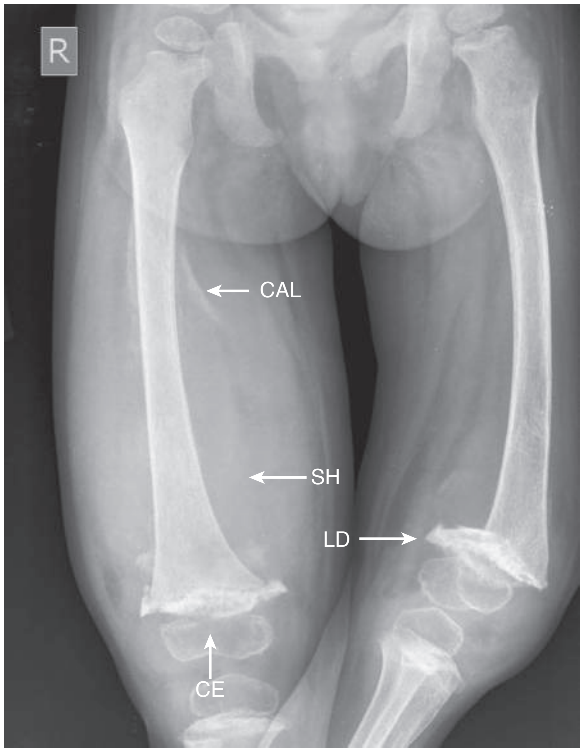

Figure 50-5 **Large subperiosteal hematoma (SH) with areas of calcification (CAL) is seen along the shaft of right femur of a child with advanced scurvy.** Epiphyseal separation is seen in both knees with linear displacement (LD) in left and compression (CE) against the shaft in right.

similar to that of scurvy. Henoch-Schönlein purpura, thrombocytopenic purpura, or leukemia is sometimes suspected in children presenting with hemorrhagic manifestations.

Treatment

Vitamin C supplements of 100-200 mg/day orally or parenterally ensure rapid and complete cure. The clinical improvement is seen within a week in most cases, but the treatment should be continued for up to 3 mo for complete recovery.

Prevention

Breastfeeding protects against vitamin C deficiency throughout infancy. In children consuming milk formula, fortification with vitamin C must be ensured. Children consuming heat-treated milk should consume adequate vitamin C–rich foods in infancy. Dietary or medicinal supplements are required in severely malnourished children, and chronic debilitating conditions such as malignancies and neurologic disorders.

TOXICITY

Daily intake of <2 g of vitamin C is generally without adverse effects in adults. Larger doses can cause gastrointestinal problems, such as abdominal pain and osmotic diarrhea. Megadoses of vitamin C should be avoided in patients with a history of urolithiasis or conditions related to excessive iron accumulation such as thalassemia and hemochromatosis. There is a paucity of data regarding vitamin C toxicity in children. The following values for tolerable upper intake levels are extrapolated from data for adults based on body weight differences: age 1-3 yr, 400 mg; age 4-8 yr, 650 mg; age 9-13 yr, 1,200 mg; and age 14-18 yr, 1,800 mg.

Chapter 51

Rickets and Hypervitaminosis D

Larry A. Greenbaum

RICKETS

Bone consists of a protein matrix called *osteoid* and a mineral phase, principally composed of calcium and phosphate, mostly in the form of hydroxyapatite. Osteomalacia is present when there is inadequate mineralization of bone osteoid and occurs in children and adults. Rickets is a disease of growing bone that is caused by unmineralized matrix at the growth plates and occurs in children only before fusion of the epiphyses. Because growth plate cartilage and osteoid continue to expand but mineralization is inadequate, the growth plate thickens. There is also an increase in the circumference of the growth plate and the metaphysis, increasing bone width at the location of the growth plates and causing some of the classic clinical manifestations, such as widening of the wrists and ankles. There is a general softening of the bones that causes them to bend easily when subject to forces such as weight bearing or muscle pull. This softening leads to a variety of bone deformities.

Rickets is principally caused by vitamin D deficiency (Table 51-1) and was rampant in northern Europe and the United States during the early years of the 20th century. Although this problem was largely corrected through public health measures that provided children with adequate vitamin D, rickets remains a persistent problem in developed countries, with many cases still secondary to preventable nutritional vitamin D deficiency. It remains a significant problem in developing countries, and may be secondary to nutritional vitamin D deficiency and inadequate intake of calcium.

Etiology

There are many causes of rickets (Table 51-2), including vitamin D disorders, calcium deficiency, phosphorous deficiency, and distal renal tubular acidosis.

Clinical Manifestations

Most manifestations of rickets are a result of skeletal changes (Table 51-3). **Craniotabes** is a softening of the cranial bones and can be detected by applying pressure at the occiput or over the parietal bones. The sensation is similar to the feel of pressing into a ping-pong ball and then releasing. Craniotabes may also be secondary to osteogenesis imperfecta, hydrocephalus, and syphilis. It is a normal finding in many newborns, especially near the suture lines, but it typically disappears within a few months of birth. Widening of the costochondral junctions results in a **rachitic rosary**, which feels like the beads of a rosary as the examiner's fingers move along the costochondral junctions from rib to rib (Fig. 51-1). **Growth plate** widening is also responsible for the enlargement at the wrists and ankles. The horizontal depression along the lower anterior chest known as **Harrison groove** occurs from pulling of the softened ribs by the diaphragm during inspiration (Fig. 51-2). Softening of the ribs also impairs air movement and predisposes patients to atelectasis and pneumonia.

There is some variation in the clinical presentation of rickets based on the etiology. Changes in the lower extremities tend to be the dominant feature in X-linked hypophosphatemic rickets. Symptoms secondary to hypocalcemia occur only in those forms of rickets associated with decreased serum calcium (Table 51-4).

The chief complaint in a child with rickets is quite variable. Many children present because of skeletal deformities, whereas others have difficulty walking owing to a combination of deformity and weakness. Other common presenting complaints include failure to thrive and symptomatic hypocalcemia (see Chapter 572).

Table 51-1 Physical and Metabolic Properties and Food Sources of the Vitamins (D, E, and K)

NAMES AND SYNONYMS	CHARACTERISTICS	BIOCHEMICAL ACTION	EFFECTS OF DEFICIENCY	EFFECTS OF EXCESS	SOURCES
VITAMIN D Vitamin D_3 (3-cholecalciferol), which is synthesized in the skin, and vitamin D_2 (from plants or yeast) are biologically equivalent; 1 μg = 40 IU vitamin D	Fat-soluble, stable to heat, acid alkali, and oxidation; bile necessary for absorption; hydroxylation in the liver and kidney necessary for biologic activity	Necessary for GI absorption of calcium; also increases absorption of phosphate; direct actions on bone, including mediating resorption	Rickets in growing children; osteomalacia; hypocalcemia can cause tetany and seizures	Hypercalcemia, which can cause emesis, anorexia, pancreatitis, hypertension, arrhythmias, CNS effects, polyuria, nephrolithiasis, renal failure	Exposure to sunlight (UV light); fish oils, fatty fish, egg yolks, and vitamin D–fortified formula, milk, cereals, bread
VITAMIN E Group of related compounds with similar biologic activities; α-tocopherol is the most potent and the most common form	Fat-soluble; readily oxidized by oxygen, iron, rancid fats; bile acids necessary for absorption	Antioxidant; protection of cell membranes from lipid peroxidation and formation of free radicals	Red cell hemolysis in premature infants; posterior column and cerebellar dysfunction; pigmentary retinopathy	Unknown	Vegetable oils, seeds, nuts, green leafy vegetables, margarine
VITAMIN K Group of naphthoquinones with similar biologic activities; K_1 (phylloquinone) from diet; K_2 (menaquinones) from intestinal bacteria	Natural compounds are fat-soluble; stable to heat and reducing agents; labile to oxidizing agent, strong acids, alkali, light; bile salts necessary for intestinal absorption	Vitamin K–dependent proteins include coagulation factors II, VII, IX, and X; proteins C, S, Z; matrix Gla protein, osteocalcin	Hemorrhagic manifestations; long-term bone and vascular health	Not established; analogs (no longer used) caused hemolytic anemia, jaundice, kernicterus, death	Green leafy vegetables, liver, certain legumes and plant oils; widely distributed

CNS, central nervous system; GI, gastrointestinal; UV, ultraviolet.

HYPOCALCEMIC SYMPTOMS†
Tetany
Seizures
Stridor due to laryngeal spasm

*These features are most commonly associated with the vitamin D–deficiency disorders.
†These symptoms develop only in children with disorders that produce hypocalcemia (see Table 51-4).

Radiology

Rachitic changes are most easily visualized on posteroanterior radiographs of the wrist, although characteristic rachitic changes can be seen at other growth plates (Figs. 51-3 and 51-4). Decreased calcification leads to thickening of the growth plate. The edge of the metaphysis loses its sharp border, which is described as *fraying*. The edge of the metaphysis changes from a convex or flat surface to a more concave surface. This change to a concave surface is termed *cupping* and is most easily seen at the distal ends of the radius, ulna, and fibula. There is widening of the distal end of the metaphysis, corresponding to the clinical observation of thickened wrists and ankles, as well as the rachitic rosary. Other radiologic features include coarse trabeculation of the diaphysis and generalized rarefaction.

Diagnosis

Most cases of rickets are diagnosed based on the presence of classic radiographic abnormalities. The diagnosis is supported by physical examination findings (see Table 51-3) and a history and laboratory test results that are consistent with a specific etiology.

Figure 51-1 Rachitic rosary in a young infant.

Clinical Evaluation

Because the majority of children with rickets have a nutritional deficiency, the initial evaluation should focus on a dietary history, emphasizing intake of vitamin D and calcium. Most children in industrialized nations receive vitamin D from formula, fortified milk, or vitamin supplements. Along with the amount, the exact composition of the formula or milk is pertinent, because rickets has occurred in children given products that are called *milk* (e.g., soy milk) but are deficient in vitamin D and/or minerals.

Cutaneous synthesis mediated by sunlight exposure is an important source of vitamin D. It is important to ask about time spent outside, sunscreen use, and clothing, especially if there may be a cultural reason for increased covering of the skin. Because winter sunlight is ineffective at stimulating cutaneous synthesis of vitamin D, the season is an additional consideration. Children with increased skin pigmentation are at increased risk for vitamin D deficiency because of decreased cutaneous synthesis.

The presence of **maternal risk** factors for nutritional vitamin D deficiency, including diet and sun exposure, is an important consideration when a neonate or young infant has rachitic findings, especially if the infant is breastfed. Determining a child's intake of dairy products, the main dietary source of calcium, provides a general sense of calcium intake. High dietary fiber can interfere with calcium absorption.

The child's **medication** use is relevant, because certain medications, such as the anticonvulsants phenobarbital and phenytoin, increase degradation of vitamin D, and aluminum-containing antacids interfere with the absorption of phosphate.

Malabsorption of vitamin D is suggested by a history of liver or intestinal disease. Undiagnosed liver or intestinal disease should be suspected if the child has gastrointestinal (GI) symptoms, although occasionally rickets is the presenting complaint. Fat malabsorption is

often associated with diarrhea or oily stools, and there may be signs or symptoms suggesting deficiencies of other fat-soluble vitamins (A, E, and K; see Chapters 48, 52, and 53).

A history of **renal disease** (proteinuria, hematuria, urinary tract infections) is an additional significant consideration, given the importance of chronic kidney disease as a cause of rickets. Polyuria can occur in children with chronic kidney disease or Fanconi syndrome.

Children with rickets might have a history of dental caries, poor growth, delayed walking, waddling gait, pneumonia, and hypocalcemic symptoms.

The family history is critical, given the large number of **genetic causes** of rickets, although most of these causes are rare. Along with bone disease, it is important to inquire about leg deformities, difficulties with walking, or unexplained short stature, because some parents may be unaware of their diagnosis. Undiagnosed disease in the mother is not unusual in X-linked hypophosphatemia. A history of a unexplained sibling death during infancy may be present in the child with cystinosis, the most common cause of Fanconi syndrome in children.

The physical examination focuses on detecting manifestations of rickets (see Table 51-3). It is important to observe the child's gait, auscultate the lungs to detect atelectasis or pneumonia, and plot the patient's growth. Alopecia suggests vitamin D–dependent rickets type 2.

The **initial laboratory** tests in a child with rickets should include serum calcium, phosphorus, alkaline phosphatase, parathyroid hormone (PTH), 25-hydroxyvitamin D, 1,25-dihydroxyvitamin D (1,25-D), creatinine, and electrolytes (see Tables 51-4 and 51-5 for interpretation). Urinalysis is useful for detecting the glycosuria and aminoaciduria (positive dipstick for protein) seen with Fanconi syndrome. Evaluation of urinary excretion of calcium (24 hr collection for calcium or calcium : creatinine ratio) is helpful if hereditary hypophosphatemic rickets with hypercalciuria or Fanconi syndrome is suspected. Direct measurement of other fat-soluble vitamins (A, E, and

K) or indirect assessment of deficiency (prothrombin time for vitamin K deficiency) is appropriate if malabsorption is a consideration.

VITAMIN D DISORDERS

Vitamin D Physiology

Vitamin D can be synthesized in skin epithelial cells and therefore technically is not a vitamin. Cutaneous synthesis is normally the most important source of vitamin D and depends on the conversion of 7-dehydrochlesterol to vitamin D_3 (3-cholecalciferol) by ultraviolet B radiation from the sun. The efficiency of this process is decreased by melanin; hence, more sun exposure is necessary for vitamin D synthesis in people with increased skin pigmentation. Measures to decrease sun exposure, such as covering the skin with clothing or applying sunscreen, also decrease vitamin D synthesis. Children who spend less time outside have reduced vitamin D synthesis. The winter sun away from the equator is ineffective at mediating vitamin D synthesis.

There are few natural dietary sources of vitamin D. Fish liver oils have a high vitamin D content. Other good dietary sources include fatty fish and egg yolks. Most children in industrialized countries receive vitamin D via fortified foods, especially formula and milk (both of which contain 400 IU/L) and some breakfast cereals and breads. Supplemental vitamin D may be vitamin D_2 (which comes from plants or yeast) or vitamin D_3. Breast milk has a low vitamin D content, approximately 12-60 IU/L.

Vitamin D is transported bound to vitamin D–binding protein to the liver, where 25-hydroxlase converts vitamin D into 25-hydroxyvitamin D (25-D), the most abundant circulating form of vitamin D. Because there is little regulation of this liver hydroxylation step, measurement of 25-D is the standard method for determining a patient's vitamin D status. The final step in activation occurs in the kidney, where 1α-hydroxylase adds a second hydroxyl group, resulting in 1,25-D. The 1α-hydroxylase is upregulated by PTH and hypophosphatemia; hyperphosphatemia and 1,25-D inhibit this enzyme. Most 1,25-D circulates bound to vitamin D–binding protein.

1,25-D acts by binding to an intracellular receptor, and the complex affects gene expression by interacting with vitamin D–response elements. In the intestine, this binding results in a marked increase in calcium absorption, which is highly dependent on 1,25-D. There is also an increase in phosphorus absorption, but this effect is less significant because most dietary phosphorus absorption is vitamin D independent. 1,25-D also has direct effects on bone, including mediating resorption. 1,25-D directly suppresses PTH secretion by the parathyroid gland, thus completing a negative feedback loop. PTH secretion is also suppressed by the increase in serum calcium mediated by 1,25-D. 1,25-D inhibits its own synthesis in the kidney and increases the synthesis of inactive metabolites.

Nutritional Vitamin D Deficiency

Vitamin D deficiency remains the most common cause of rickets globally and is prevalent, even in industrialized countries. Because vitamin D can be obtained from dietary sources or from cutaneous synthesis, most patients in industrialized countries have a combination of risk factors that lead to vitamin D deficiency.

Etiology

Vitamin D deficiency most commonly occurs in infancy because of a combination of poor intake and inadequate cutaneous synthesis. Transplacental transport of vitamin D, mostly 25-D, typically provides enough vitamin D for the 1st 2 mo of life unless there is severe maternal vitamin D deficiency. Infants who receive formula receive adequate vitamin D, even without cutaneous synthesis. Because of the low vitamin D content of breast milk, breastfed infants rely on cutaneous synthesis or vitamin supplements. Cutaneous synthesis can be limited because of the ineffectiveness of the winter sun in stimulating vitamin D synthesis; avoidance of sunlight because of concerns about cancer, neighborhood safety, or cultural practices; and decreased cutaneous synthesis because of increased skin pigmentation.

The effect of skin pigmentation explains why most cases of nutritional rickets in the United States and northern Europe occur in breastfed children of African descent or other dark-pigmented populations. The additional impact of the winter sun is supported by the fact that such infants more commonly present in the late winter or spring. In some groups, complete covering of infants or the practice of not taking infants outside has a significant role, explaining the occurrence of rickets in infants living in areas of abundant sunshine, such as the Middle East. Because the mothers of some infants can have the same risk factors, decreased maternal vitamin D can also contribute, both by leading to reduced vitamin D content in breast milk and by lessening transplacental delivery of vitamin D. Rickets caused by vitamin D deficiency can also be secondary to unconventional dietary practices, such as vegan diets that use unfortified soy milk or rice milk.

Clinical Manifestations

The clinical features are typical of rickets (see Table 51-3), with a significant minority presenting with symptoms of hypocalcemia; prolonged laryngospasm is occasionally fatal. These children have an increased risk of pneumonia and muscle weakness leading to a delay in motor development.

Laboratory Findings

Tables 51-4 and 51-5 summarize the principal laboratory findings. Hypocalcemia is a variable finding as a result of the actions of the elevated PTH to increase the serum calcium concentration. The hypophosphatemia is caused by PTH-induced renal losses of phosphate, combined with a decrease in intestinal absorption.

The wide variation in 1,25-D levels (low, normal, or high) is secondary to the upregulation of renal 1α-hydroxylase caused by concomitant hypophosphatemia and hyperparathyroidism. Because serum levels of 1,25-D are much lower than the levels of 25-D, even with low levels of 25-D there is still often enough 25-D present to act as a precursor for 1,25-D synthesis in the presence of an upregulated 1α-hydroxylase. The level of 1,25-D is only low when there is severe vitamin D deficiency.

Some patients have a metabolic acidosis secondary to PTH-induced renal bicarbonate wasting. There may also be generalized aminoaciduria.

Diagnosis and Differential Diagnosis

The diagnosis of nutritional vitamin D deficiency is based on the combination of a history of poor vitamin D intake and risk factors for decreased cutaneous synthesis, radiographic changes consistent with rickets, and typical laboratory findings (see Tables 51-4 and 51-5). A normal PTH level almost never occurs with vitamin D deficiency and suggests a primary phosphate disorder.

Treatment

Children with nutritional vitamin D deficiency should receive vitamin D and adequate nutritional intake of calcium and phosphorus. There are 2 strategies for administration of vitamin D. With stoss therapy, 300,000-600,000 IU of vitamin D are administered orally or intramuscularly as 2-4 doses over 1 day. Because the doses are observed, stoss therapy is ideal in situations where adherence to therapy is questionable. The alternative is daily, high-dose vitamin D, with doses ranging from 2,000-5,000 IU/day over 4-6 wk. Either strategy should be followed by daily vitamin D intake of 400 IU/day if <1 yr old or 600 IU/day if >1 yr old. It is important to ensure that children receive adequate dietary calcium and phosphorus; this dietary intake is usually provided by milk, formula, and other dairy products.

Children who have symptomatic hypocalcemia might need intravenous calcium acutely, followed by oral calcium supplements, which typically can be tapered over 2-6 wk in children who receive adequate dietary calcium. Transient use of intravenous or oral 1,25-D (calcitriol) is often helpful in reversing hypocalcemia in the acute phase by providing active vitamin D during the delay as supplemental vitamin D is converted to active vitamin D. Calcitriol doses are typically 0.05 μg/kg/day. Intravenous calcium is initially given as an acute bolus for symptomatic hypocalcemia (20 mg/kg of calcium

chloride or 100 mg/kg of calcium gluconate). Some patients require a continuous intravenous calcium drip, titrated to maintain the desired serum calcium level. These patients should transition to enteral calcium, and most infants require approximately 1,000 mg of elemental calcium.

Prognosis

Most children have an excellent response to treatment, with radiologic healing occurring within a few months. Laboratory test results should also normalize rapidly. Many of the bone malformations improve dramatically, but children with severe disease can have permanent deformities and short stature. Rarely, patients benefit from orthopedic intervention for leg deformities, although this is generally not done until the metabolic bone disease has healed, there is clear evidence that the deformity will not self-resolve, and the deformity is causing functional problems.

Prevention

Most cases of nutritional rickets can be prevented by universal administration of 400 IU of vitamin D to infants who are breastfed. Older children should receive 600 IU/day. Vitamin D may be administered as a component of a multivitamin or as a vitamin D supplement.

Congenital Vitamin D Deficiency

Congenital rickets is quite rare in industrialized countries and occurs when there is severe maternal vitamin D deficiency during pregnancy. Maternal risk factors include poor dietary intake of vitamin D, lack of adequate sun exposure, and closely spaced pregnancies. These newborns can have symptomatic hypocalcemia, intrauterine growth retardation, and decreased bone ossification, along with classic rachitic changes. More subtle maternal vitamin D deficiency can have an adverse effect on neonatal bone density and birthweight, cause a defect in dental enamel, and predispose infants to neonatal hypocalcemic tetany. Treatment of congenital rickets includes vitamin D supplementation and adequate intake of calcium and phosphorus. Use of prenatal vitamins containing vitamin D prevents this entity.

Secondary Vitamin D Deficiency

Etiology

Along with inadequate intake, vitamin D deficiency can develop due to inadequate absorption, decreased hydroxylation in the liver, and increased degradation. Because vitamin D is fat-soluble, its absorption may be decreased in patients with a variety of liver and GI diseases, including cholestatic liver disease, defects in bile acid metabolism, cystic fibrosis and other causes of pancreatic dysfunction, celiac disease, and Crohn disease. Malabsorption of vitamin D can also occur with intestinal lymphangiectasia and after intestinal resection.

Severe liver disease, which is usually also associated with malabsorption, can cause a decrease in 25-D formation as a consequence of insufficient enzyme activity. Because of the large reserve of 25-hydroxlase activity in the liver, vitamin D deficiency as a result of liver disease usually requires a loss of >90% of liver function. A variety of medications increase the degradation of vitamin D by inducing the cytochrome P450 system. Rickets as a consequence of vitamin D deficiency can develop in children receiving anticonvulsants, such as phenobarbital or phenytoin, or antituberculosis medications, such as isoniazid or rifampin.

Treatment

Treatment of vitamin D deficiency attributable to malabsorption requires high doses of vitamin D. Because of its better absorption, 25-D (25-50 μg/day or 5-7 μg/kg/day) is superior to vitamin D_3. The dose is adjusted based on monitoring of serum levels of 25-D. Alternatively, patients may be treated with 1,25-D, which also is better absorbed in the presence of fat malabsorption, or with parenteral vitamin D. Children with rickets as a result of increased degradation of vitamin D by the cytochrome P450 system require the same acute therapy as indicated for nutritional deficiency (discussed earlier), followed by long-term administration of high doses of vitamin D (e.g., 1,000 IU/day), with dosing titrated based on serum levels of 25-D. Some patients require as much as 4,000 IU/day.

Vitamin D–Dependent Rickets, Type 1

Children with vitamin D–dependent rickets type 1, an autosomal recessive disorder, have mutations in the gene encoding renal 1α-hydroxylase, preventing conversion of 25-D into 1,25-D. These patients normally present during the 1st 2 yr of life and can have any of the classic features of rickets (see Table 51-3), including symptomatic hypocalcemia. They have normal levels of 25-D, but low levels of 1,25-D (see Table 51-5). Occasionally, 1,25-D levels are at the lower limit of normal, inappropriately low given the high PTH and low serum phosphorus levels, both of which should increase the activity of renal 1α-hydroxylase and cause elevated levels of 1,25-D. As in nutritional vitamin D deficiency, renal tubular dysfunction can cause a metabolic acidosis and generalized aminoaciduria.

Treatment

These patients respond to long-term treatment with 1,25-D (calcitriol). Initial doses are 0.25-2 μg/day, and lower doses are used once the rickets has healed. Especially during initial therapy, it is important to ensure adequate intake of calcium. The dose of calcitriol is adjusted to maintain a low-normal serum calcium level, a normal serum phosphorus level, and a high-normal serum PTH level. Targeting a low-normal calcium concentration and a high-normal PTH level avoids excessive dosing of calcitriol, which can cause hypercalciuria and nephrocalcinosis. Hence, patient monitoring includes periodic assessment of urinary calcium excretion, with a target of <4 mg/kg/day.

Vitamin D–Dependent Rickets, Type 2

Patients with vitamin D–dependent rickets type 2 have mutations in the gene encoding the vitamin D receptor, preventing a normal physiologic response to 1,25-D. Levels of 1,25-D are extremely elevated in this autosomal recessive disorder (see Table 51-4). Most patients present during infancy, although rickets in less severely affected patients might not be diagnosed until adulthood. Less-severe disease is associated with a partially functional vitamin D receptor. Approximately 50-70% of children have **alopecia**, which tends to be associated with a more severe form of the disease and can range from alopecia areata to alopecia totalis. Epidermal cysts are a less common manifestation.

Treatment

Some patients respond to extremely high doses of vitamin D_2, 25-D or 1,25-D, especially patients without alopecia. This response is due to a partially functional vitamin D receptor. All patients with this disorder should be given a 3-6 mo trial of high-dose vitamin D and oral calcium. The initial dose of 1,25-D should be 2 μg/day, but some patients require doses as high as 50-60 μg/day. Calcium doses are 1,000-3,000 mg/day. Patients who do not respond to high-dose vitamin D may be treated with long-term intravenous calcium, with possible transition to very high dose oral calcium supplements. Treatment of patients who do not respond to vitamin D is difficult.

Chronic Kidney Disease (See Chapter 535.2)

With chronic kidney disease, there is decreased activity of 1α-hydroxylase in the kidney, leading to diminished production of 1,25-D. In chronic kidney disease, unlike the other causes of vitamin D deficiency, patients have hyperphosphatemia as a result of decreased renal excretion (see Table 51-4).

Treatment

Therapy requires the use of a form of vitamin D that can act without 1-hydroxylation by the kidney (calcitriol), which both permits adequate absorption of calcium and directly suppresses the parathyroid gland. Because hyperphosphatemia is a stimulus for PTH secretion, normalization of the serum phosphorus level via a combination of dietary phosphorus restriction and the use of oral phosphate binders is as important as the use of activated vitamin D.

CALCIUM DEFICIENCY

Pathophysiology

Rickets secondary to inadequate dietary calcium is a significant problem in some countries in Africa, although there are cases in other regions of the world, including industrialized countries. Because breast milk and formula are excellent sources of calcium, this form of rickets develops after children have been weaned from breast milk or formula and is more likely to occur in children who are weaned early. Rickets develops because the diet has low calcium content, typically <200 mg/day. There is little intake of dairy products or other sources of calcium. In addition, because of reliance on grains and green leafy vegetables, the diet may be high in phytate, oxalate, and phosphate, which decrease absorption of dietary calcium. In industrialized countries, rickets caused by calcium deficiency can occur in children who consume an unconventional diet. Examples include children with milk allergy who have low dietary calcium and children who transition from formula or breast milk to juice, soda, or a calcium-poor soy drink, without an alternative source of dietary calcium.

This type of rickets can develop in children who receive intravenous nutrition without adequate calcium. Malabsorption of calcium can occur in celiac disease, intestinal abetalipoproteinemia, and after small bowel resection. There may be concurrent malabsorption of vitamin D.

Clinical Manifestations

Children have the classic signs and symptoms of rickets (see Table 51-3). Presentation can occur during infancy or early childhood, although some cases are diagnosed in teenagers. Because calcium deficiency occurs after the cessation of breastfeeding, it tends to occur later than the nutritional vitamin D deficiency that is associated with breastfeeding. In Nigeria, nutritional vitamin D deficiency is most common at 4-15 mo of age, whereas calcium-deficiency rickets typically occurs at 15-25 mo of age.

Diagnosis

Laboratory findings include increased levels of alkaline phosphatase, PTH, and 1,25-D (see Table 51-4). Calcium levels may be normal or low, although symptomatic hypocalcemia is uncommon. There is decreased urinary excretion of calcium, and serum phosphorus levels may be low as a result of renal wasting of phosphate from secondary hyperparathyroidism. In some children, there is coexisting nutritional vitamin D deficiency, with low 25-D levels.

Treatment

Treatment focuses on providing adequate calcium, typically as a dietary supplement (doses of 700 [1-3 yr age], 1,000 [4-8 yr age], 1,300 [9-18 yr age] mg/day of elemental calcium are effective). Vitamin D supplementation is necessary if there is concurrent vitamin D deficiency (discussed earlier). Prevention strategies include discouraging early cessation of breastfeeding and increasing dietary sources of calcium. In countries such as Kenya, where many children have diets high in cereal with negligible intake of cow's milk, school-based milk programs have been effective in reducing the prevalence of rickets.

PHOSPHOROUS DEFICIENCY

Inadequate Intake

With the exception of starvation or severe anorexia, it is almost impossible to have a diet that is deficient in phosphorus, because phosphorus is present in most foods. Decreased phosphorus absorption can occur in diseases associated with malabsorption (celiac disease, cystic fibrosis, cholestatic liver disease), but if rickets develops, the primary problem is usually malabsorption of vitamin D and/or calcium.

Isolated malabsorption of phosphorus occurs in patients with long-term use of aluminum-containing antacids. These compounds are very effective at chelating phosphate in the GI tract, leading to decreased absorption. This decreased absorption results in hypophosphatemia with secondary osteomalacia in adults and rickets in children. This entity responds to discontinuation of the antacid and short-term phosphorus supplementation.

Fibroblast Growth Factor-23

Fibroblast growth factor-23 (FGF-23) is a humoral mediator that decreases renal tubular reabsorption of phosphate and therefore decreases serum phosphorus. FGF-23, synthesized by osteocytes, also decreases the activity of renal 1α-hydroxylase, resulting in a decrease in the production of 1,25-D. Increased levels of FGF-23 cause many of the renal phosphate-wasting diseases (see Table 51-2).

X-Linked Hypophosphatemic Rickets

Among the genetic disorders causing rickets because of hypophosphatemia, X-linked hypophosphatemic rickets (XLH) is the most common, with a prevalence of 1/20,000. The defective gene is on the X chromosome, but female carriers are affected, so it is an X-linked dominant disorder.

Pathophysiology

The defective gene is called *PHEX* because it is a **PH**osphate-regulating gene with homology to **E**ndopeptidases on the **X** chromosome. The product of this gene appears to have an indirect role in inactivating FGF-23. Mutations in the *PHEX* gene lead to increased levels of FGF-23. Because the actions of FGF-23 include inhibition of phosphate reabsorption in the proximal tubule, phosphate excretion is increased. FGF-23 also inhibits renal 1α-hydroxylase, leading to decreased production of 1,25-D.

Clinical Manifestations

These patients have rickets, but abnormalities of the lower extremities and poor growth are the dominant features. Delayed dentition and tooth abscesses are also common. Some patients have hypophosphatemia and short stature without clinically evident bone disease.

Laboratory Findings

Patients have high renal excretion of phosphate, hypophosphatemia, and increased alkaline phosphatase; PTH and serum calcium levels are normal (see Table 51-4). Hypophosphatemia normally upregulates renal 1α-hydroxylase and should lead to an increase in 1,25-D, but these patients have low or inappropriately normal levels of 1,25-D.

Treatment

Patients respond well to a combination of oral phosphorus and 1,25-D (calcitriol). The daily need for phosphorus supplementation is 1-3 g of elemental phosphorus divided into 4-5 doses. Frequent dosing helps to prevent prolonged decrements in serum phosphorus because there is a rapid decline after each dose. In addition, frequent dosing decreases diarrhea, a complication of high-dose oral phosphorus. Calcitrol is administered 30-70 ng/kg/day divided into 2 doses.

Complications of treatment occur when there is not an adequate balance between phosphorus supplementation and calcitriol. Excess phosphorus, by decreasing enteral calcium absorption, leads to secondary hyperparathyroidism, with worsening of the bone lesions. In contrast, excess calcitriol causes hypercalciuria and nephrocalcinosis and can even cause hypercalcemia. Hence, laboratory monitoring of treatment includes serum calcium, phosphorus, alkaline phosphatase, PTH, and urinary calcium, as well as periodic renal ultrasounds to evaluate patients for nephrocalcinosis. Because of variation in the serum phosphorus level and the importance of avoiding excessive phosphorus dosing, normalization of alkaline phosphatase levels is a more useful method of assessing the therapeutic response than measuring serum phosphorus. For children with significant short stature, growth hormone is an effective option. Children with severe deformities might need osteotomies, but these procedures should be done only when treatment has led to resolution of the bone disease.

Prognosis

The response to therapy is usually good, although frequent dosing can lead to problems with compliance. Girls generally have less-severe disease than boys, probably because of the X-linked inheritance. Short stature can persist despite healing of the rickets. Adults generally do well with less-aggressive treatment, and some receive calcitriol alone.

Adults with bone pain or other symptoms improve with oral phosphorus supplementation and calcitriol.

Autosomal Dominant Hypophosphatemic Rickets

Autosomal dominant hypophosphatemic rickets (ADHR) is much less common than XLH. There is incomplete penetrance and variable age of onset. Patients with ADHR have a mutation in the gene encoding FGF-23 (*FGF23*). The mutation prevents degradation of FGF-23 by proteases, leading its level to increase. The actions of FGF-23 include decreased reabsorption of phosphate in the renal proximal tubule, which results in hypophosphatemia, and inhibition of the 1α-hydroxylase in the kidney, causing a decrease in 1,25-D synthesis.

In ADHR, as in XLH, abnormal laboratory findings are hypophosphatemia, an elevated alkaline phosphatase level, and a low or inappropriately normal 1,25-D level (see Table 51-4). Treatment is similar to the approach used in XLH.

Autosomal Recessive Hypophosphatemic Rickets

Autosomal recessive hypophosphatemic rickets (ARHR), type 1 is an extremely rare disorder caused by mutations in the gene encoding dentin matrix protein 1 (*DMP1*). ARHR, type 2 occurs in patients with mutations in the *ENPP1* gene. Mutations in *ENPP1* also cause generalized arterial calcification of infancy. Both types of ARHR are associated with elevated levels of FGF-23, leading to renal phosphate wasting, hypophosphatemia, and low or inappropriately normal levels of 1,25-D. Treatment is similar to the approach used in XLH, although monitoring for arterial calcification is prudent in patients with *ENPP1* mutations.

Hereditary Hypophosphatemic Rickets with Hypercalciuria

Hereditary hypophosphatemic rickets with hypercalciuria is a rare disorder that is mainly found in the Middle East.

Pathophysiology

This autosomal recessive disorder is caused by mutations in the gene for a sodium-phosphate cotransporter in the proximal tubule (*SLC34A3*). The renal phosphate leak causes hypophosphatemia, which then stimulates production of 1,25-D. The high level of 1,25-D increases intestinal absorption of calcium, suppressing PTH. Hypercalciuria ensues as a result of the high absorption of calcium and the low level of PTH, which normally decreases renal excretion of calcium.

Clinical Manifestations

The dominant symptoms are rachitic leg abnormalities (see Table 51-3), muscle weakness, and bone pain. Patients can have short stature, with a disproportionate decrease in the length of the lower extremities. The severity of the disease varies, and some family members have no evidence of rickets but have kidney stones secondary to hypercalciuria.

Laboratory Findings

Laboratory findings include hypophosphatemia, renal phosphate wasting, elevated serum alkaline phosphatase levels, and elevated 1,25-D levels. PTH levels are low (see Table 51-4).

Treatment

Therapy relies on oral phosphorus replacement (1-2.5 g/day of elemental phosphorus in 5 divided oral doses). Treatment of the hypophosphatemia decreases serum levels of 1,25-D and corrects the hypercalciuria. The response to therapy is usually excellent, with resolution of pain, weakness, and radiographic evidence of rickets.

Overproduction of FGF-23

Tumor-induced osteomalacia is more common in adults than in children, where it can produce classic rachitic findings. Most tumors are mesenchymal in origin and are usually benign, small, and located in bone. These tumors secrete FGF-23 and produce a biochemical phenotype that is similar to XLH, including urinary phosphate wasting, hypophosphatemia, elevated alkaline phosphatase levels, and low or inappropriately normal 1,25-D levels (see Table 51-4). Curative treatment is excision of the tumor. If the tumor cannot be removed, treatment is identical to that used for XLH.

Renal phosphate wasting leading to hypophosphatemia and rickets (or osteomalacia in adults) is a potential complication in **McCune-Albright syndrome,** an entity that includes the triad of polyostotic fibrous dysplasia, hyperpigmented macules, and polyendocrinopathy (see Chapter 563.6). Affected patients have inappropriately low levels of 1,25-D and elevated levels of alkaline phosphatase. The renal phosphate wasting and inhibition of 1,25-D synthesis are related to the polyostotic fibrous dysplasia. Patients have elevated levels of FGF-23, presumably produced by the dysplastic bone. Hypophosphatemic rickets can also occur in children with isolated polyostotic fibrous dysplasia. Although it is rarely possible, removal of the abnormal bone can cure this disorder in children with McCune-Albright syndrome. Most patients receive the same treatment as children with XLH. Bisphosphonate treatment decreases the pain and fracture risk associated with the bone lesions.

Rickets is an unusual complication of **epidermal nevus syndrome** (see Chapter 651). Patients have hypophosphatemic rickets due to renal phosphate wasting and also have an inappropriately normal or low level of 1,25-D as a consequence of excessive production of FGF-23. The timing of presentation with rickets varies from infancy to early adolescence. Resolution of hypophosphatemia and rickets has occurred after excision of the epidermal nevi in some patients, but not in others. In most cases, the skin lesions are too extensive to be removed, necessitating treatment with phosphorus supplementation and 1,25-D. Rickets caused by phosphate wasting is an extremely rare complication in children with **neurofibromatosis** (see Chapter 596.1).

Fanconi Syndrome

Fanconi syndrome is secondary to generalized dysfunction of the renal proximal tubule (see Chapter 529.1). There are renal losses of phosphate, amino acids, bicarbonate, glucose, urate, and other molecules that are normally reabsorbed in the proximal tubule. Some patients have partial dysfunction, with less generalized losses. The most clinically relevant consequences are hypophosphatemia caused by phosphate losses and proximal renal tubular acidosis caused by bicarbonate losses. Patients have rickets as a result of hypophosphatemia, with exacerbation from the chronic metabolic acidosis, which causes bone dissolution. Failure to thrive is a consequence of both rickets and renal tubular acidosis. Treatment is dictated by the etiology (see Chapter 529).

Dent Disease (See Chapter 531.3)

Dent disease is an X-linked disorder usually caused by mutations in the gene encoding a chloride channel that is expressed in the kidney (CLCN5). Some patients have mutations in the *OCRL 1* gene, which can also cause Lowe syndrome (see Chapter 530.1). Affected males have variable manifestations, including hematuria, nephrolithiasis, nephrocalcinosis, rickets, and chronic kidney disease. Almost all patients have low-molecular-weight proteinuria and hypercalciuria. Other, less universal abnormalities are aminoaciduria, glycosuria, hypophosphatemia, and hypokalemia. Rickets occurs in approximately 25% of patients, and it responds to oral phosphorus supplements. Some patients also need 1,25-D, but this treatment should be used cautiously because it can worsen the hypercalciuria.

RICKETS OF PREMATURITY (See Chapter 106)

Rickets in very-low-birthweight infants has become a significant problem, as the survival rate for this group of infants has increased.

Pathogenesis

The transfer of calcium and phosphorus from mother to fetus occurs throughout pregnancy, but 80% occurs during the 3rd trimester. Premature birth interrupts this process, with rickets developing when the

premature infant does not have an adequate supply of calcium and phosphorus to support mineralization of the growing skeleton.

Most cases of rickets of prematurity occur in infants with a birthweight <1,000 g. It is more likely to develop in infants with lower birthweight and younger gestational age. Rickets occurs because unsupplemented breast milk and standard infant formula do not contain enough calcium and phosphorus to supply the needs of the premature infant. Other risk factors include cholestatic jaundice, a complicated neonatal course, prolonged use of parenteral nutrition, the use of soy formula, and medications such as diuretics and corticosteroids.

Clinical Manifestations

Rickets of prematurity occurs 1-4 mo after birth. Infants can have nontraumatic fractures, especially of the legs, arms, and ribs. Most fractures are not suspected clinically. Because fractures and softening of the ribs lead to decreased chest compliance, some infants have respiratory distress due to atelectasis and poor ventilation. This rachitic respiratory distress usually develops >5 wk after birth, distinguishing it from the early-onset respiratory disease of premature infants. These infants have poor linear growth, with negative effects on growth persisting beyond 1 yr of age. An additional long-term effect is enamel hypoplasia. Poor bone mineralization can contribute to dolichocephaly. There may be classic rachitic findings, such as frontal bossing, rachitic rosary, craniotabes, and widened wrists and ankles (see Table 51-3). Most infants with rickets of prematurity have no clinical manifestations, and the diagnosis is based on radiographic and laboratory findings.

Laboratory Findings

Because of inadequate intake, the serum phosphorus level is low or low-normal in rickets of prematurity. The renal response is appropriate, with conservation of phosphate leading to a low urine phosphate level; the tubular reabsorption of phosphate is >95%. Most patients have normal levels of 25-D, unless there has been inadequate intake or poor absorption (discussed earlier). The hypophosphatemia stimulates renal 1α-hydroxylase, so levels of 1,25-D are high or high-normal. These high levels can contribute to bone demineralization, because 1,25-D stimulates bone resorption. Serum levels of calcium are low, normal, or high, and patients often have hypercalciuria. Elevated serum calcium levels and hypercalciuria are secondary to increased intestinal absorption and bone dissolution owing to elevation of 1,25-D levels and the inability to deposit calcium in bone because of an inadequate phosphorus supply. The hypercalciuria indicates that phosphorus is the limiting nutrient for bone mineralization, although increased provision of phosphorus alone often cannot correct the mineralization defect; increased calcium is also necessary. Hence, there is an inadequate supply of calcium and phosphorus, but the deficiency in phosphorus is greater.

Alkaline phosphatase levels are often elevated, but some affected infants have normal levels. In some instances, normal alkaline phosphatase levels may be secondary to resolution of the bone demineralization because of an adequate mineral supply despite the continued presence of radiologic changes, which take longer to resolve. However, alkaline phosphatase levels may be normal despite active disease. No single blood test is 100% sensitive for the diagnosis of rickets. The diagnosis should be suspected in infants with an alkaline phosphatase level that is >5-6 times the upper limit of normal for adults (unless there is concomitant liver disease) or a phosphorus level <5.6 mg/dL. The diagnosis is confirmed by radiologic evidence of rickets, which is best seen on films of the wrists and ankles. Films of the arms and legs might reveal fractures. The rachitic rosary may be visible on chest x-ray. Unfortunately, x-rays cannot show early demineralization of bone because changes are not evident until there is >20-30% reduction in the bone mineral content.

Diagnosis

Because many premature infants have no overt clinical manifestations of rickets, screening tests are recommended. These tests should include weekly measurements of calcium, phosphorus, and alkaline phosphatase. Periodic measurement of the serum bicarbonate concentration is also important, because metabolic acidosis causes dissolution of bone. At least 1 screening x-ray for rickets at 6-8 wk of age is appropriate in infants who are at high risk for rickets; additional films may be indicated in very high risk infants.

Prevention

Provision of adequate amounts of calcium, phosphorus, and vitamin D significantly decreases the risk of rickets of prematurity. Parenteral nutrition is often necessary initially in very premature infants. In the past, adequate parenteral calcium and phosphorus delivery was difficult because of limits secondary to insolubility of these ions when their concentrations were increased. Current amino acid preparations allow higher concentrations of calcium and phosphate, decreasing the risk of rickets. Early transition to enteral feedings is also helpful. These infants should receive either human milk fortified with calcium and phosphorus or preterm infant formula, which has higher concentrations of calcium and phosphorus than standard formula. Soy formula should be avoided because there is decreased bioavailability of calcium and phosphorus. Increased mineral feedings should continue until the infant weighs 3-3.5 kg. These infants should also receive approximately 400 IU/day of vitamin D via formula and vitamin supplements.

Treatment

Therapy for rickets of prematurity focuses on ensuring adequate delivery of calcium, phosphorus, and vitamin D. If mineral delivery has been good and there is no evidence of healing, then it is important to screen for vitamin D deficiency by measuring serum 25-D. Measurement of PTH, 1,25-D, and urinary calcium and phosphorus may be helpful in some cases.

DISTAL RENAL TUBULAR ACIDOSIS
(See Chapter 530)

Distal renal tubular acidosis usually manifests with failure to thrive. Patients have a metabolic acidosis with an inability to acidify the urine appropriately. Hypercalciuria and nephrocalcinosis are typically present. There are many possible etiologies, including autosomal recessive and autosomal dominant forms. Rickets is variable, and it responds to alkali therapy (see Fig. 51-4).

HYPERVITAMINOSIS D

Etiology

Hypervitaminosis D is secondary to excessive intake of vitamin D. It can occur with long-term high intake or with a substantial, acute ingestion (see Table 51-1). Most cases are secondary to misuse of prescribed or nonprescription vitamin D supplements, but other cases have been secondary to accidental overfortification of milk, contamination of table sugar, and inadvertent use of vitamin D supplements as cooking oil. The recommended upper limits for long-term vitamin D intake are 1,000 IU for children <1 year old and 2,000 IU for older children and adults. Hypervitaminosis D can also result from excessive intake of synthetic vitamin D analogs (25-D, 1,25-D). Vitamin D intoxication is never secondary to excessive exposure to sunlight, probably because ultraviolet irradiation can transform vitamin D_3 and its precursor into inactive metabolites.

Pathogenesis

Although vitamin D increases intestinal absorption of calcium, the dominant mechanism of the hypercalcemia is excessive bone resorption.

Clinical Manifestations

The signs and symptoms of vitamin D intoxication are secondary to hypercalcemia. GI manifestations include nausea, vomiting, poor feeding, constipation, abdominal pain, and pancreatitis. Possible cardiac findings are hypertension, decreased Q-T interval, and arrhythmias. The central nervous system effects of hypercalcemia include lethargy, hypotonia, confusion, disorientation, depression, psychosis, hallucinations, and coma. Hypercalcemia impairs renal concentrating

mechanisms, which can lead to polyuria, dehydration, and hypernatremia. Hypercalcemia can also lead to acute renal failure, nephrolithiasis, and nephrocalcinosis, which can result in chronic renal insufficiency. Deaths are usually associated with arrhythmias or dehydration.

Laboratory Findings

The classic findings in vitamin D intoxication are hypercalcemia and extremely elevated levels of 25-D (>150 ng/mL). Hyperphosphatemia is also common. PTH levels are appropriately decreased owing to hypercalcemia. Hypercalciuria is universally present and can lead to nephrocalcinosis, which is visible on renal ultrasound. Hypercalcemia and nephrocalcinosis can lead to renal insufficiency.

Surprisingly, levels of 1,25-D are usually normal. This may be a result of downregulation of renal 1α-hydroxylase by the combination of low PTH, hyperphosphatemia, and a direct effect of 1,25-D. There is evidence indicating that the level of free 1,25-D may be high, owing to displacement from vitamin D–binding proteins by 25-D. Nephrocalcinosis is often visible on ultrasound or CT scan. Anemia is sometimes present; the mechanism is unknown.

Diagnosis and Differential Diagnosis

The diagnosis is based on the presence of hypercalcemia and an elevated serum 25-D level, although children with excess intake of 1,25-D or another synthetic vitamin D preparation have normal levels of 25-D. With careful sleuthing, there is usually a history of excess intake of vitamin D, although in some situations (overfortification of milk by a dairy) the patient and family may be unaware.

The **differential diagnosis** of vitamin D intoxication focuses on other causes of hypercalcemia. **Hyperparathyroidism** produces hypophosphatemia, whereas vitamin D intoxication usually causes hyperphosphatemia. **Williams syndrome** is often suggested by phenotypic features and accompanying cardiac disease. **Idiopathic infantile hypercalcemia** occurs in children taking appropriate doses of vitamin D. **Subcutaneous fat necrosis** is a common cause of hypercalcemia in young infants; skin findings are usually present. The hypercalcemia of **familial benign hypocalciuric hypercalcemia** is mild, asymptomatic, and associated with hypocalciuria. Hypercalcemia of **malignancy** is an important consideration. High intake of calcium can also cause hypercalcemia, especially in the presence of renal insufficiency. Questioning about calcium intake should be part of the history in a patient with hypercalcemia. Occasionally, patients are intentionally taking high doses of calcium and vitamin D.

Treatment

The treatment of vitamin D intoxication focuses on control of hypercalcemia. Many patients with hypercalcemia are dehydrated as a result of polyuria from nephrogenic diabetes insipidus, poor oral intake, and vomiting. Rehydration lowers the serum calcium level via dilution and corrects prerenal azotemia. The resultant increased urine output increases urinary calcium excretion. Urinary calcium excretion is also increased by high urinary sodium excretion. The mainstay of the initial treatment is aggressive therapy with normal saline, often in conjunction with a loop diuretic to further increase calcium excretion.

Normal saline, with or without a loop diuretic, is often adequate for treating mild or moderate hypercalcemia. More significant hypercalcemia usually requires other therapies. Glucocorticoids decrease intestinal absorption of calcium by blocking the action of 1,25-D. There is also a decrease in the levels of 25-D and 1,25-D. The usual dosage of prednisone is 1-2 mg/kg/24 hr.

Calcitonin, which lowers calcium by inhibiting bone resorption, is a useful adjunct, but its effect is usually not dramatic. There is an excellent response to intravenous or oral bisphosphonates in vitamin D intoxication. Bisphosphonates inhibit bone resorption through their effects on osteoclasts. Hemodialysis using a low or 0 dialysate calcium can rapidly lower serum calcium in patients with severe hypercalcemia that is refractory to other measures.

Along with controlling hypercalcemia, it is imperative to eliminate the source of excess vitamin D. Additional sources of vitamin D such as multivitamins and fortified foods should be eliminated or reduced. Avoidance of sun exposure, including the use of sunscreen, is prudent. The patient should also restrict calcium intake.

Prognosis

Most children make a full recovery, but hypervitaminosis D may be fatal or can lead to chronic kidney disease. Because vitamin D is stored in fat, levels can remain elevated for months, necessitating regular monitoring of 25-D, serum calcium, and urine calcium.

Chapter 52

Vitamin E Deficiency

Larry A. Greenbaum

Vitamin E is a fat-soluble vitamin and functions as an antioxidant, but its precise biochemical functions are not known. Vitamin E deficiency can cause hemolysis or neurologic manifestations and occurs in premature infants, in patients with malabsorption, and in an autosomal recessive disorder affecting vitamin E transport. Because of its role as an antioxidant, there is considerable research on the potential role of vitamin E supplementation in chronic illnesses.

PATHOGENESIS

The term *vitamin E* denotes a group of 8 compounds with similar structures and antioxidant activity. The most potent member of these compounds is α-tocopherol, which is also the main form in humans. The best dietary sources of vitamin E are vegetable oils, seeds, nuts, green leafy vegetables, and margarine (see Table 51-1).

The majority of vitamin E is located within cell membranes, where it prevents lipid peroxidation and the formation of free radicals. Other antioxidants, such as ascorbic acid, enhance the antioxidant activity of vitamin E. The importance of other functions of vitamin E is still being delineated.

Premature infants are particularly susceptible to vitamin E deficiency, because there is significant transfer of vitamin E during the last trimester of pregnancy. Vitamin E deficiency in premature infants causes thrombocytosis, edema, and hemolysis potentially causing anemia. The risk of symptomatic vitamin E deficiency was increased by the use of formulas for premature infants that had a high content of polyunsaturated fatty acids (PUFAs). These formulas led to a high content of PUFAs in red blood cell membranes, making them more susceptible to oxidative stress, which could be ameliorated by vitamin E. Oxidative stress was augmented by aggressive use of iron supplementation; iron increases the production of oxygen radicals. The incidence of hemolysis as a result of vitamin E deficiency in premature infants decreased secondary to the use of formulas with a lower content of PUFAs, less-aggressive use of iron, and provision of adequate vitamin E.

Because vitamin E is plentiful in common foods, primary dietary deficiency is rare except in premature infants and in severe, generalized malnutrition. Vitamin E deficiency does occur in children with fat malabsorption secondary to the need for bile acid for vitamin E absorption. Although symptomatic disease is most common in children with cholestatic liver disease, it can occur in patients with cystic fibrosis, celiac disease, short-bowel syndrome, or Crohn disease. The autosomal recessive disorder **abetalipoproteinemia** (see Chapter 86) causes fat malabsorption, and vitamin E deficiency is a common complication.

In **ataxia with isolated vitamin E deficiency** (AVED), a rare autosomal recessive disorder, there are mutations in the gene for α-tocopherol transfer protein (*TTPA*). Patients with this disorder are unable to incorporate vitamin E into lipoproteins before their release from the liver, leading to reduced serum levels of vitamin E. There is no associated fat malabsorption, and absorption of vitamin E from the intestine occurs normally.

CLINICAL MANIFESTATIONS

A severe, progressive neurologic disorder occurs in patients with prolonged vitamin E deficiency. Clinical manifestations do not appear until after 1 yr of age, even in children with cholestasis since birth. Patients may have cerebellar disease, posterior column dysfunction, and retinal disease. Loss of deep tendon reflexes is usually the initial finding. Subsequent manifestations include limb ataxia (intention tremor, dysdiadochokinesia), truncal ataxia (wide-based, unsteady gait), dysarthria, ophthalmoplegia (limited upward gaze), nystagmus, decreased proprioception (positive Romberg test), decreased vibratory sensation, and dysarthria. Some patients have pigmentary retinopathy. Visual field constriction can progress to blindness. Cognition and behavior can also be affected. Myopathy and cardiac arrhythmias are less-common findings.

In premature infants, hemolysis as a result of vitamin E deficiency typically develops during the 2nd mo of life. Edema may also be present.

LABORATORY FINDINGS

Serum vitamin E levels increase in the presence of high serum lipid levels, even when vitamin E deficiency is present. Hence, vitamin E status is best determined by measuring the ratio of vitamin E to serum lipids; a ratio <0.8 mg/g is abnormal in older children and adults; <0.6 mg/g is abnormal in infants <1 yr. Premature infants with hemolysis caused by vitamin E deficiency also often have elevated platelet counts.

Neurologic involvement can cause abnormal somatosensory evoked potentials and nerve conduction studies. Abnormalities on electroretinography can precede physical examination findings in patients with retinal involvement.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Premature infants with unexplained hemolytic anemia after the 1st mo of life, especially if thrombocytosis is present, either should be empirically treated with vitamin E or should have serum vitamin E and lipid levels measured. Children with neurologic findings and a disease that causes fat malabsorption should have their vitamin E status evaluated.

Because children with AVED do not have symptoms of malabsorption, a correct diagnosis requires a high index of suspicion. **Friedreich ataxia** has been misdiagnosed in some patients (see Chapter 597.1). Children with unexplained ataxia should be screened for vitamin E deficiency.

TREATMENT

For correction of deficiency in neonates, the dose of vitamin E is 25-50 units/day for 1 wk, followed by adequate dietary intake. Children with deficiency as a result of malabsorption should receive 1 unit/kg/day, with the dose adjusted based on levels; ongoing treatment is necessary. Children with AVED normalize their serum vitamin E levels with high doses of vitamin E and require ongoing treatment.

PROGNOSIS

The hemolytic anemia in infants resolves with correction of the vitamin E deficiency. Some neurologic manifestations of vitamin E deficiency may be reversible with early treatment, but many patients have little or no improvement. Importantly, treatment prevents progression.

PREVENTION

Premature infants should receive sufficient vitamin E via formula or breast milk fortifier and formula without a high content of PUFAs. Children at risk for vitamin E deficiency as a result of malabsorption should be screened for deficiency and given adequate vitamin E supplementation. Vitamin preparations with high content of all of the fat-soluble vitamins are available.

Chapter 53

Vitamin K Deficiency

Larry A. Greenbaum

Vitamin K is necessary for the synthesis of clotting factors II, VII, IX, and X; deficiency of vitamin K can result in clinically significant bleeding. Vitamin K deficiency typically affects infants, who experience a transient deficiency related to inadequate intake, or patients of any age who have decreased vitamin K absorption. Mild vitamin K deficiency can affect long-term bone and vascular health (see Chapters 103.4 and 480).

PATHOGENESIS

Vitamin K is a group of compounds that have a common naphthoquinone ring structure. Phylloquinone, called *vitamin* K_1, is present in a variety of dietary sources, with green leafy vegetables, liver, and certain legumes and plant oils having the highest content. Vitamin K_1 is the form used to fortify foods and as a medication in the United States. Vitamin K_2 is a group of compounds called *menaquinones*, which are produced by intestinal bacteria. There is uncertainty regarding the relative importance of intestinally produced vitamin K_2. Menaquinones are also present in meat, especially liver, and cheese. A menaquinone is used pharmacologically in some countries.

Vitamin K is a cofactor for γ-glutamyl carboxylase, an enzyme that performs posttranslational carboxylation, converting glutamate residues in proteins to γ-carboxyglutamate (Gla). The Gla residues, by facilitating calcium binding, are necessary for protein function.

The classic Gla-containing proteins involved in blood coagulation that are decreased in vitamin K deficiency are factors II (prothrombin), VII, IX, and X. Vitamin K deficiency causes a decrease in proteins C and S, which inhibit blood coagulation, and protein Z, which also has a role in coagulation. All of these proteins are made only in the liver, except for protein S, a product of various tissues.

Gla-containing proteins are also involved in bone biology (e.g., osteocalcin and protein S) and vascular biology (matrix Gla protein and protein S). Based on the presence of reduced levels of Gla, these proteins appear more sensitive than the coagulation proteins to subtle vitamin K deficiency. There is evidence suggesting that mild vitamin K deficiency might have a deleterious effect on long-term bone strength and vascular health.

Because it is fat soluble, vitamin K requires the presence of bile salts for its absorption. Unlike other fat-soluble vitamins, there are limited body stores of vitamin K. In addition, there is high turnover of vitamin K, and the vitamin K–dependent clotting factors have a short half-life. Hence, symptomatic vitamin K deficiency can develop within weeks when there is inadequate supply because of low intake or malabsorption.

There are 3 forms of **vitamin K–deficiency bleeding** (VKDB) of the newborn (see Chapter 103.4). Early VKDB was formerly called *classic hemorrhagic disease of the newborn* and occurs at 1-14 days of age. Early VKDB is secondary to low stores of vitamin K at birth as a result of the poor transfer of vitamin K across the placenta and inadequate intake during the 1st few days of life. In addition, there is no intestinal synthesis of vitamin K_2 because the newborn gut is sterile. Early VKDB

occurs mostly in breastfed infants as a consequence of the low vitamin K content of breast milk (formula is fortified). Delayed feeding is an additional risk factor.

Late VKDB most commonly occurs at 2-12 wk of age, although cases can occur up to 6 mo after birth. Almost all cases are in breastfed infants because of the low vitamin K content of breast milk. An additional risk factor is occult malabsorption of vitamin K, as occurs in children with undiagnosed cystic fibrosis or cholestatic liver disease (e.g., biliary atresia, α_1-antitrypsin deficiency). Without vitamin K prophylaxis, the incidence is 4-10/100,000 newborns.

The third form of VKDB of the newborn occurs at birth or shortly thereafter. It is secondary to maternal intake of medications (warfarin, phenobarbital, phenytoin) that cross the placenta and interfere with vitamin K function.

VKDB as a result of fat malabsorption can occur in children of any age. Potential etiologies include cholestatic liver disease, pancreatic disease, and intestinal disorders (celiac sprue, inflammatory bowel disease, short-bowel syndrome). Prolonged diarrhea can cause vitamin K deficiency, especially in breastfed infants. Children with cystic fibrosis are most likely to have vitamin K deficiency if they have pancreatic insufficiency and liver disease.

Beyond infancy, low dietary intake by itself never causes vitamin K deficiency. However, the combination of poor intake and the use of broad-spectrum antibiotics that eliminate the intestine's vitamin K_2-producing bacteria can cause vitamin K deficiency. This scenario is especially common in the intensive care unit. Vitamin K deficiency can also occur in patients who receive total parenteral nutrition without vitamin K supplementation.

CLINICAL MANIFESTATIONS

In early VKDB, the most common sites of bleeding are the gastrointestinal (GI) tract, mucosal and cutaneous tissue, the umbilical stump, and the postcircumcision site; intracranial bleeding is less common. GI blood loss can be severe enough to require a transfusion. In contrast, the most common site of bleeding in late VKDB is intracranial, although cutaneous and GI bleeding may be the initial manifestation. Intracranial bleeding can cause convulsions, permanent neurologic sequelae, or death. In some cases of late VKDB, the presence of an underlying disorder may be suggested by jaundice or failure to thrive. Older children with vitamin K deficiency can present with bruising, mucocutaneous bleeding, or more serious bleeding.

LABORATORY FINDINGS

In patients with bleeding as a result of vitamin K deficiency, the prothrombin time (PT) is prolonged. The PT must be interpreted based on the patient's age, because it is normally prolonged in newborns (see Chapter 476). The partial thromboplastin time is usually prolonged, but it may be normal in early deficiency; factor VII has the shortest half-life of the coagulation factors and is the first to be affected by vitamin K deficiency, but isolated factor VII deficiency does not affect the partial thromboplastin time. The platelet count and fibrinogen level are normal.

When there is mild vitamin K deficiency, the PT is normal, but there are elevated levels of the undercarboxylated forms of the proteins that are normally carboxylated in the presence of vitamin K. These undercarboxylated proteins are called *proteins induced by vitamin K absence* (PIVKA). Measurement of undercarboxylated factor II (PIVKA-II) can be used to detect mild vitamin K deficiency. Determination of blood vitamin K levels is less useful because of significant variation based on recent dietary intake; levels do not always reflect tissue stores.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis is established by the presence of a prolonged PT that corrects rapidly after administration of vitamin K, which stops the active bleeding. Other possible causes of bleeding and a prolonged PT include **disseminated intravascular coagulation** (DIC), liver failure, and rare hereditary deficiencies of clotting factors. DIC, which is most commonly secondary to sepsis, is associated with thrombocytopenia, low fibrinogen, and elevated D-dimers. Most patients with DIC have hemodynamic instability that does not correct with restoration of blood volume. Severe liver disease results in decreased production of clotting factors; the PT does not fully correct with administration of vitamin K. Children with a hereditary disorder have a deficiency in a specific clotting factor (I, II, V, VII, X).

Coumarin derivatives inhibit the action of vitamin K by preventing its recycling to an active form after it functions as a cofactor for γ-glutamyl carboxylase. Bleeding can occur with overdosage of the commonly used anticoagulant warfarin or with ingestion of rodent poison, which contains a coumarin derivative. High doses of salicylates also inhibit vitamin K regeneration, potentially leading to a prolonged PT and clinical bleeding.

TREATMENT

Infants with VKDB should receive 1 mg of parenteral vitamin K. The PT should decrease within 6 hr and normalize within 24 hr. For rapid correction in adolescents, the parenteral dose is 2.5-10 mg. In addition to vitamin K, a patient with severe, life-threatening bleeding should receive an infusion of fresh-frozen plasma, which corrects the coagulopathy rapidly. Children with vitamin K deficiency as a consequence of malabsorption require chronic administration of high doses of oral vitamin K (2.5 mg twice/wk to 5 mg/day). Parenteral vitamin K may be necessary if oral vitamin K is ineffective.

PREVENTION

Administration of either oral or parenteral vitamin K soon after birth prevents early VKDB of the newborn. In contrast, a single dose of oral vitamin K does not prevent a substantial number of cases of late VKDB. However, a single intramuscular injection of vitamin K (1 mg), the current practice in the United States, is almost universally effective, except in children with severe malabsorption. This increased efficacy of the intramuscular form is thought to be the result of a depot effect. Concerns about an association between parenteral vitamin K at birth and the later development of malignancy are unsubstantiated.

Discontinuing the offending medications before delivery can prevent VKDB attributable to maternal medications. If this is not possible, administration of vitamin K to the mother may be helpful. In addition, the neonate should receive parenteral vitamin K immediately after birth. If parenteral vitamin K does not correct the coagulopathy rapidly, then the child should receive fresh frozen plasma.

Children who are at high risk for malabsorption of vitamin K should receive supplemental vitamin K and periodic measurement of the PT.

Chapter **54**

Micronutrient Mineral Deficiencies

Larry A. Greenbaum

Micronutrients include vitamins (see Chapters 48-53) and trace elements. By definition, a trace element is <0.01% of the body weight. Trace elements have a variety of essential functions (Table 54-1). With the exception of iron deficiency, trace element deficiency (see Table 54-1) is uncommon in developed countries, but some deficiencies (iodine, zinc, selenium) are important public health problems in a number of developing countries. Because of low nutritional requirements and plentiful supply, deficiencies of some of the trace elements are extremely rare in humans and typically occur in patients receiving

Table 54-1 Trace Elements

ELEMENT	PHYSIOLOGY	EFFECTS OF DEFICIENCY	EFFECTS OF EXCESS	DIETARY SOURCES
Chromium	Potentiates the action of insulin	Impaired glucose tolerance, peripheral neuropathy, and encephalopathy	Unknown	Meat, grains, fruits, and vegetables
Copper	Absorbed via specific intestinal transporter Circulates bound to ceruloplasmin Enzyme cofactor (superoxide dismutase, cytochrome oxidase, and enzymes involved in iron metabolism and connective tissue formation)	Microcytic anemia, osteoporosis, neutropenia, neurologic symptoms, depigmentation of hair and skin	Acute: nausea, emesis, abdominal pain, coma, and hepatic necrosis Chronic toxicity (liver and brain injury) occurs in Wilson disease (see Chapter 357.2) and secondary to excess intake (see Chapter 357.3)	Vegetables, grains, nuts, liver, margarine, legumes, corn oil
Fluoride	Incorporated into bone	Dental caries (see Chapter 312)	Chronic: dental fluorosis (see Chapter 307)	Toothpaste, fluoridated water
Iodine	Component of thyroid hormone (see Chapter 564)	Hypothyroidism (see Chapters 566 and 568)	Hypothyroidism and goiter (see Chapters 566 and 568); maternal excess can cause congenital hypothyroidism and goiter (see Chapter 568.1)	Saltwater fish, iodized salt
Iron	Component of hemoglobin, myoglobin, cytochromes, and other enzymes	Anemia (see Chapter 456), decreased alertness, impaired learning	Acute (see Chapter 63): nausea, vomiting, diarrhea, abdominal pain, and hypotension Chronic excess usually secondary to hereditary disorders (see Chapters 463.9 and 357.4); causes organ dysfunction	Meat, fortified foods Deficiency can also result from blood loss (hookworm infestation, menorrhagia)
Manganese	Enzyme cofactor	Hypercholesterolemia, weight loss, decreased clotting proteins*	Neurologic manifestations, cholestatic jaundice	Nuts, meat, grains, tea
Molybdenum	Enzyme cofactor (xanthine oxidase and others)	Tachycardia, tachypnea, night blindness, irritability, coma*	Hyperuricemia and increased risk of gout	Legumes, grains, liver
Selenium	Enzyme cofactor (prevents oxidative damage)	Cardiomyopathy (Keshan disease), myopathy	Nausea, diarrhea, neurologic manifestations, nail and hair changes, garlic odor	Meat, seafood, whole grains, garlic
Zinc	Enzyme cofactor Constituent of zinc-finger proteins, which regulate gene transcription	Decreased growth, dermatitis of extremities and around orifices, impaired immunity, poor wound healing, hypogonadism, diarrhea Supplements beneficial in diarrhea and improve neurodevelopmental outcomes	Abdominal pain, diarrhea, vomiting Can worsen copper deficiency	Meat, shellfish, whole grains, legumes, cheese

*These deficiency states have been reported only in case reports associated with parenteral nutrition or highly unusual diets.

unusual diets or prolonged total parenteral nutrition without adequate delivery of a specific trace element. They can also occur in children with short bowel or malabsorption. Excess intake of trace elements (see Table 54-1) is uncommon, but it can result from environmental exposure or overuse of supplements.

For a number of reasons, children are especially susceptible to trace element deficiency. First, growth creates an increased demand for most trace elements. Second, some organs are more likely to sustain permanent damage because of trace element deficiency during childhood. The developing brain is particularly vulnerable to the consequences of certain deficiency states (iron, iodide). Similarly, adequate fluoride is most critical for dental health during childhood. Third, children, especially in the developing world, are more prone to gastrointestinal disorders that can cause trace element deficiencies because of malabsorption.

A normal diet provides adequate intake of most trace elements. However, the intake of certain trace elements varies significantly in different geographic locations. Iodide-containing food is plentiful near the ocean, but inland areas often have inadequate sources, leading to goiter and **hypothyroidism.** Iodine deficiency is not a problem in the United States because of the widespread use of iodized salt; however, symptomatic iodine deficiency (goiter and hypothyroidism) is common in many developing countries. Selenium content of the soil and consequently of food is also quite variable. Dietary selenium deficiency (associated with cardiomyopathy) occurs in certain locations, such as some parts of China.

The consequences of severe isolated trace mineral deficiency are illustrated in certain genetic disorders. The manifestations of **Menkes disease** (see Chapters 357.5 and 599) are caused by a mutation in the gene coding for a protein that facilitates intestinal copper absorption. This mutation results in severe copper deficiency; subcutaneous copper is an effective treatment. The recessive disorder **acrodermatitis enteropathica** (see Chapter 671) is secondary to malabsorption of zinc. These patients respond dramatically to zinc supplementation.

Children can have apparently asymptomatic deficiencies of certain trace elements but still benefit from supplementation. As an example, zinc is highly effective in treating children before or during diarrheal illnesses in the developing world.

Zinc deficiency is quite common in the developing world and is often associated with malnutrition or other micronutrient deficiencies (iron). Chronic zinc deficiency is associated with dwarfism, hypogonadism, dermatitis, and T-cell immunodeficiency. Diets rich in phytates bind zinc, impairing its absorption. Zinc supplementation in at-risk children reduces the incidence and severity of diarrhea, pneumonia, and possibly malaria. In developing countries, children who have diarrhea may benefit from zinc supplementation, especially if there is underlying malnutrition.

Fluid and Electrolyte Disorders

PART VII

Chapter 55
Electrolyte and Acid-Base Disorders

55.1 Composition of Body Fluids

Larry A. Greenbaum

TOTAL BODY WATER

Total body water (TBW) as a percentage of body weight varies with age (Fig. 55-1). The fetus has very high TBW, which gradually decreases to approximately 75% of birthweight for a term infant. Premature infants have higher TBW than term infants. During the 1st yr of life, TBW decreases to approximately 60% of body weight and basically remains at this level until puberty. At puberty, the fat content of females increases more than that in males, who acquire more muscle mass than females. Because fat has very low water content and muscle has high water content, by the end of puberty TBW in males remains at 60%, but TBW in females decreases to approximately 50% of body weight. The high fat content in overweight children causes a decrease in TBW as a percentage of body weight. During dehydration, TBW decreases and, thus, is a smaller percentage of body weight.

FLUID COMPARTMENTS

TBW is divided between 2 main compartments: intracellular fluid (ICF) and extracellular fluid (ECF). In the fetus and newborn, the ECF volume is larger than the ICF volume (see Fig. 55-1). The normal postnatal diuresis causes an immediate decrease in the ECF volume. This is followed by continued expansion of the ICF volume, which results from cellular growth. By 1 yr of age, the ratio of the ICF volume to the ECF volume approaches adult levels. The ECF volume is approximately 20-25% of body weight, and the ICF volume is approximately 30-40% of body weight, close to twice the ECF volume (Fig. 55-2). With puberty, the increased muscle mass of males causes them to have a higher ICF volume than females. There is no significant difference in the ECF volume between postpubertal females and males.

The ECF is further divided into the plasma water and the interstitial fluid (see Fig. 55-2). The plasma water is 5% of body weight. The blood volume, given a hematocrit of 40%, is usually 8% of body weight, although it is higher in newborns and young infants; in premature newborns, it is approximately 10% of body weight. The volume of plasma water can be altered by pathologic conditions, including dehydration, anemia, polycythemia, heart failure, abnormal plasma osmolality, and hypoalbuminemia. The interstitial fluid, normally 15% of body weight, can increase dramatically in diseases associated with edema, such as heart failure, protein-losing enteropathy, liver failure, nephrotic syndrome, and sepsis. An increase in interstitial fluid also occurs in patients with ascites or pleural effusions.

There is a delicate equilibrium between the intravascular fluid and the interstitial fluid. The balance between hydrostatic and oncotic forces regulates the intravascular volume, which is critical for proper tissue perfusion. The intravascular fluid has a higher concentration of albumin than the interstitial fluid, and the consequent oncotic force draws water into the intravascular space. The maintenance of this gradient depends on the limited permeability of albumin across the capillaries. The hydrostatic pressure of the intravascular space, which is due to the pumping action of the heart, drives fluid out of the intravascular space. These forces favor movement into the interstitial space at the arterial ends of the capillaries. The decreased hydrostatic forces and increased oncotic forces, which result from the dilutional increase in albumin concentration, cause movement of fluid into the venous ends of the capillaries. Overall, there is usually a net movement of fluid out of the intravascular space to the interstitial space, but this fluid is returned to the circulation via the **lymphatics.** An imbalance in these forces may cause expansion of the interstitial volume at the expense of the intravascular volume. In children with hypoalbuminemia, the decreased oncotic pressure of the intravascular fluid contributes to the development of **edema.** Loss of fluid from the intravascular space may compromise the intravascular volume, placing the child at risk for inadequate blood flow to vital organs. This is especially likely in diseases in which capillary leak occurs because the loss of albumin from the intravascular space is associated with an increase in the albumin concentration in the interstitial space, further compromising the oncotic forces that normally maintain intravascular volume. In contrast, with **heart failure,** there is an increase in venous hydrostatic pressure from expansion of the intravascular volume, which is caused by impaired pumping by the heart, and the increase in venous pressure causes fluid to move from the intravascular space to the interstitial space. Expansion of the intravascular volume and increased intravascular pressure also cause the edema that occurs with acute glomerulonephritis.

ELECTROLYTE COMPOSITION

The composition of the solutes in the ICF and ECF are very different (Fig. 55-3). Sodium and chloride are the dominant cation and anion, respectively, in the ECF. The sodium and chloride concentrations in the ICF are much lower. Potassium is the most abundant cation in the ICF, and its concentration within the cells is approximately 30 times higher than in the ECF. Proteins, organic anions, and phosphate are the most plentiful anions in the ICF. The dissimilarity between the anions in the ICF and the ECF is largely determined by the presence of intracellular molecules that do not cross the cell membrane, the barrier separating the ECF and the ICF. In contrast, the difference in the distribution of cations—sodium and potassium—is a result of the activity of the Na^+,K^+-adenosine triphosphatase (ATPase) pump, which uses cellular energy to actively extrude sodium from cells and move potassium into cells. The chemical gradient between the intracellular potassium concentration and the extracellular potassium concentration creates the electrical gradient across the cell membrane. The concentration-dependent movement of potassium out of the cell makes the intracellular space negative relative to the extracellular space.

The difference in the electrolyte compositions of the ECF and the ICF has important ramifications in the evaluation and treatment of electrolyte disorders. The serum concentration of an electrolyte, which is measured clinically, does not always reflect the body content. This is because of the larger volume of the ICF compared with the ECF and the variation in electrolyte concentrations between these 2 compartments. The intracellular potassium concentration is much higher than the serum concentration. A shift of potassium from the intracellular space can maintain a normal or even an elevated serum potassium concentration, despite massive losses of potassium from the intracellular space. This is dramatically seen in diabetic ketoacidosis, in which a state of significant potassium depletion is often masked because of a transmembrane shift of potassium from the ICF to the ECF. For potassium and phosphorus, electrolytes with a high intracellular concentration, the serum level may not reflect total body content. Similarly, the serum calcium concentration does not predict the body content of calcium, which is largely in bone.

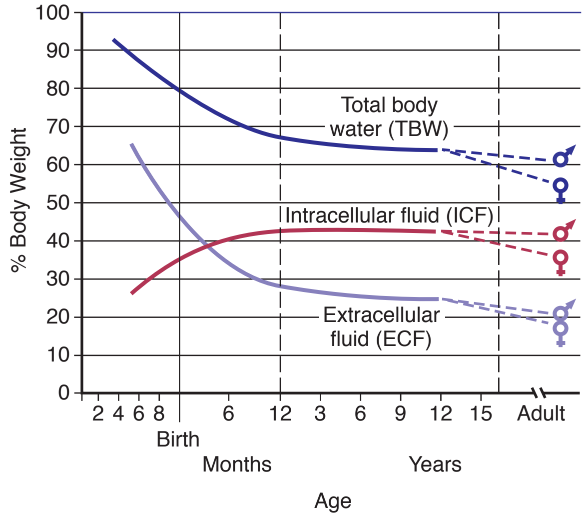

Figure 55-1 Total body water, intracellular fluid, and extracellular fluid as a percentage of body weight and a function of age. *(From Winters RW: Water and electrolyte regulation. In Winters RW, editor:* The body fluids in pediatrics, *Boston, 1973, Little, Brown.)*

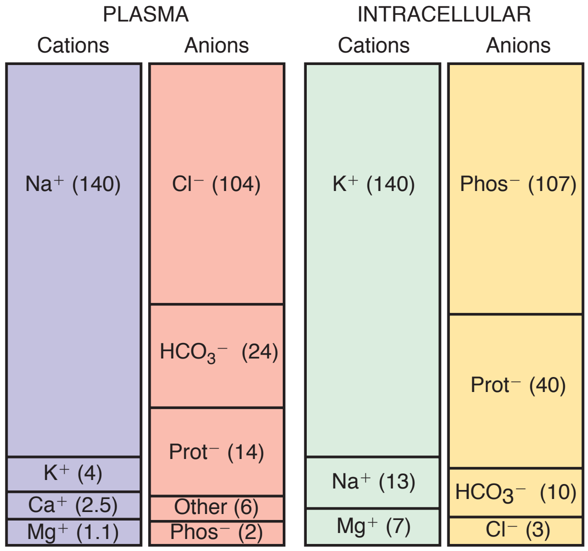

Figure 55-3 The concentrations of the major cations and anions in the intracellular space and the plasma, expressed in mEq/L.

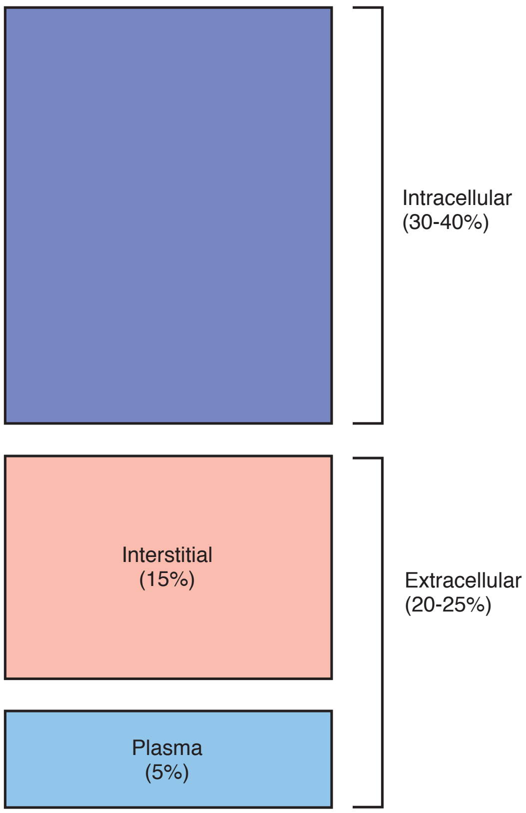

Figure 55-2 Compartments of total body water, expressed as percentages of body weight, in an older child or adult.

OSMOLALITY

The ICF and the ECF are in **osmotic equilibrium** because the cell membrane is permeable to water. If the osmolality in 1 compartment changes, then water movement leads to a rapid equalization of osmolality. This can lead to significant shifts of water between the intracellular space and the extracellular space. Clinically, the primary process is usually a change in the osmolality of the ECF, with a resultant shift of water into the ICF if the ECF osmolality decreases or a shift of water out of the ICF if the ECF osmolality increases. *The osmolality of the ECF can be determined, and it usually equals the ICF osmolality*. The plasma osmolality is normally 285-295 mOsm/kg, and it is measured by the degree of freezing point depression. The plasma osmolality can also be *estimated* by a calculation based on the following formula:

$$\text{Osmolality} = 2 \times [\text{Na}] + [\text{glucose}]/18 + [\text{BUN}]/2.8$$

Glucose and blood urea nitrogen (BUN) are measured in mg/dL. Division of these values by 18 and 2.8, respectively, as shown, converts the units into mmol/L. Multiplication of the sodium value by 2 accounts for its accompanying anions, principally chloride and bicarbonate. The calculated osmolality is usually slightly lower than the measured osmolality.

Glucose and urea normally contribute little to the plasma osmolality; multiplication of the sodium value by 2 provides an approximation of the osmolality. Urea is not confined to the extracellular space because it readily crosses the cell membrane and its intracellular concentration approximately equals its extracellular concentration. Whereas an elevated sodium concentration causes a shift of water from the intracellular space, with uremia, there is no osmolar gradient between the 2 compartments and, consequently, no movement of water. The only exception is during **hemodialysis,** when the decrease in extracellular urea is so rapid that the intracellular urea does not have time to equilibrate. This may lead to the **disequilibrium syndrome,** in which water shifts into brain cells, potentially causing severe symptoms. Ethanol, because it freely crosses cell membranes, is another ineffective osmole. The effective osmolality can be calculated as follows:

$$\text{Effective osmolality} = 2 \times [\text{Na}] + [\text{glucose}]/18$$

The effective osmolality (also called the tonicity) determines the osmotic force that is mediating the shift of water between the ECF and the ICF.

Hyperglycemia causes an increase in the plasma osmolality because it is not in equilibrium with the intracellular space. During hyperglycemia there is a shift of water from the intracellular space to the extracellular space. This is clinically important in children with hyperglycemia during diabetic ketoacidosis. The shift of water causes dilution of the sodium in the extracellular space, causing hyponatremia despite an elevated plasma osmolality. The magnitude of this effect can be calculated as follows:

$$[\text{Na}]_{\text{corrected}} = [\text{Na}]_{\text{measured}} + 1.6 \times ([\text{glucose}] - 100\ \text{mg/dL})/100$$

where $[Na]_{measured}$ = sodium concentration measured by the clinical laboratory and $[Na]_{corrected}$ = corrected sodium concentration (the

sodium concentration if the glucose concentration were normal and its accompanying water moved back into the cells). The $[Na]_{corrected}$ is the more reliable indicator of the patient's true ratio of total body sodium to TBW, the normal determinant of the sodium concentration.

Normally, the measured osmolality and the calculated osmolality are within 10 mOsm/kg. However, there are some clinical situations in which this does not occur. The presence of **unmeasured osmoles** causes the measured osmolality to be significantly elevated in comparison with the calculated osmolality. This difference is the **osmolal gap,** which is present when the measured osmolality exceeds the calculated osmolality by >10 mOsm/kg. Examples of unmeasured osmoles include ethanol, ethylene glycol, methanol, sucrose, sorbitol, and mannitol. These substances increase the measured osmolality but are not part of the equation for calculating osmolality. The presence of an osmolal gap is a clinical clue to the presence of unmeasured osmoles and may be diagnostically useful when there is clinical suspicion of poisoning with methanol or ethylene glycol.

Pseudohyponatremia is a second situation in which there is discordance between the measured osmolality and the calculated osmolality. Lipids and proteins are the solids of the serum. In patients with elevated serum lipids or proteins, the water content of the serum decreases because water is displaced by the larger amount of solids. Some instruments measure sodium concentration by determining the amount of sodium per liter of serum, including the solid component. When the solid component increases, there is a decrease in the sodium concentration per liter of serum, despite a normal concentration of sodium when based on the amount of sodium per liter of serum water. *It is the concentration of sodium in serum water that is physiologically relevant.* A similar problem occurs when using instruments that require dilution of the sample prior to measurement of sodium (indirect potentiometry). In both situations, the plasma osmolality is normal despite the presence of pseudohyponatremia, because the method for measuring osmolality is not appreciably influenced by the percentage of serum that is composed of lipids and proteins. Pseudohyponatremia is diagnosed by the finding of a normal measured plasma osmolality despite hyponatremia. This laboratory artifact does not occur if the sodium concentration in water is measured directly with an ion-specific electrode, such as occurs with the instruments used for measuring arterial blood gases. **Pseudohypernatremia** may occur in patients with very low levels of serum proteins via a similar mechanism.

When there are no unmeasured osmoles and pseudohyponatremia is not a concern, the calculated osmolality provides an accurate estimate of the plasma osmolality. Measurement of plasma osmolality is useful for detecting or monitoring unmeasured osmoles and confirming the presence of true hyponatremia. Whereas many children with high plasma osmolality are dehydrated—as seen with hypernatremic dehydration or diabetic ketoacidosis—high osmolality does not always equate with dehydration. A child with **salt poisoning** or **uremia** has an elevated plasma osmolality but may be volume overloaded. In many situations, it is best to focus on the components of the plasma osmolality and to analyze them individually to reach a correct clinical conclusion.

Bibliography is available at Expert Consult.

55.2 Regulation of Osmolality and Volume

Larry A. Greenbaum

The regulation of plasma *osmolality* and the intravascular *volume* is controlled by independent systems for water balance, which determines osmolality, and sodium balance, which determines volume status. Maintenance of normal osmolality depends on control of water balance. Control of volume status depends on regulation of sodium balance. When volume depletion is present, it takes precedence over regulation of osmolality, and retention of water contributes to the maintenance of intravascular volume.

REGULATION OF OSMOLALITY

The plasma osmolality is tightly regulated and maintained at 285-295 mOsm/kg. Modification of water intake and excretion maintains normal plasma osmolality. In the steady state, the combination of water intake and water produced by the body from oxidation balances water losses from the skin, lungs, urine, and gastrointestinal tract. Only water intake and urinary losses can be regulated.

Osmoreceptors in the hypothalamus sense the plasma osmolality (see Chapter 556). An elevated effective osmolality leads to secretion of antidiuretic hormone (ADH) by neurons in the supraoptic and paraventricular nuclei in the hypothalamus. The axons of these neurons terminate in the posterior pituitary. Circulating ADH binds to its V_2 receptors in the collecting duct cells of the kidney, and, via the generation of cyclic adenosine monophosphate, causes insertion of water channels (aquaporin-2) into the renal collecting ducts. This produces increased permeability to water, permitting resorption of water into the hypertonic renal medulla. The end result is that the urine concentration increases and water excretion decreases. Urinary water losses cannot be completely eliminated because there is obligatory excretion of urinary solutes, such as urea and sodium. The regulation of ADH secretion is tightly linked to plasma osmolality, responses being detectable with a 1% change in the osmolality. ADH secretion virtually disappears when the plasma osmolality is low, allowing excretion of maximally dilute urine. The consequent loss of **free water** (water without sodium) corrects the plasma osmolality. ADH secretion is not an all-or-nothing response; there is a graded adjustment as the osmolality changes.

Production of concentrated urine under the control of ADH requires a hypertonic renal medulla. The countercurrent multiplier, produced by the loop of Henle and the vasa recta, generates this hypertonicity. ADH stimulates sodium transport in the loop of Henle, helping to maintain this gradient when water retention is necessary.

Water intake is regulated by hypothalamic osmoreceptors, although these are different from the osmoreceptors that determine ADH secretion. These hypothalamic osmoreceptors, by linking to the cerebral cortex, stimulate thirst when the serum osmolality increases. Thirst occurs with a small increase in the serum osmolality.

Control of osmolality is subordinate to maintenance of an adequate intravascular volume. When volume depletion is present, both ADH secretion and thirst are stimulated, regardless of the plasma osmolality. The sensation of thirst requires moderate volume depletion but only a 1-2% change in the plasma osmolality. Although all of the mechanisms are not clear, angiotensin II, which is increased during volume depletion, is known to stimulate thirst. Baroreceptors, when sensing volume depletion, may also stimulate thirst.

A number of conditions can limit the kidney's ability to excrete adequate water to correct low plasma osmolality. In the **syndrome of inappropriate antidiuretic hormone (SIADH),** ADH continues to be produced despite a low plasma osmolality. In the presence of ADH, urinary dilution does not occur, and sufficient water is not excreted (see Chapters 55.3 and 559).

The glomerular filtration rate (GFR) affects the kidney's ability to eliminate water. With a decrease in the GFR, less water is delivered to the collecting duct, limiting the amount of water that can be excreted. The impairment in the GFR must be quite significant to limit the kidney's ability to respond to an excess of water.

The **minimum urine osmolality** is approximately 30-50 mOsm/kg. This places an upper limit on the kidney's ability to excrete water; sufficient solute must be present to permit water loss. Massive water intoxication may exceed this limit, whereas a lesser amount of water is necessary in the child with a diet that has very little solute. This is occasionally seen and can produce severe hyponatremia in children who receive little salt and have little urea production as a result of inadequate protein intake. Volume depletion is an extremely important cause of decreased water loss by the kidney despite a low plasma osmolality. This "appropriate" secretion of ADH occurs because volume depletion takes precedence over the osmolality in the regulation of ADH.

The normal response to increased plasma osmolality is conservation of water by the kidney. In **central diabetes insipidus,** this does not

occur because of an absence of ADH secretion (see Chapters 55.3 and 558). Patients with **nephrogenic diabetes insipidus** have an inability to respond to ADH and produce dilute urine despite an increase in plasma osmolality (see Chapters 55.3 and 530).

The **maximum urine osmolality** is approximately 1,200 mOsm/kg. The obligatory solute losses dictate the minimum volume of urine that must be produced, even when maximally concentrated. Obligatory water losses increase in patients with high salt intake or high urea losses, as may occur after relief of a urinary obstruction or during recovery from acute tubular necrosis. An increase in urinary solute and, consequently, water losses occurs with an **osmotic diuresis,** which occurs classically from glycosuria in diabetes mellitus as well as iatrogenically after mannitol administration. There are developmental changes in the kidney's ability to concentrate the urine. The maximum urine osmolality in a newborn, especially a premature newborn, is less than that in an older infant or child. This limits the ability to conserve water and makes such a patient more vulnerable to hypernatremic dehydration. Very high fluid intake, as seen with **psychogenic polydipsia,** can dilute the high osmolality in the renal medulla, which is necessary for maximal urinary concentration. If fluid intake is restricted in patients with this condition, there may be some impairment in the kidney's ability to concentrate the urine, although this defect corrects after a few days without polydipsia. This may also occur during the initial treatment of central diabetes insipidus with desmopressin acetate; the renal medulla takes time to achieve its normal maximum osmolality. Loop diuretics, such as furosemide, by inhibiting sodium resorption in the ascending limb of the loop of Henle, decrease medullary hypertonicity, preventing excretion of maximally concentrated urine.

REGULATION OF VOLUME

An appropriate intravascular volume is critical for survival; both volume depletion and volume overload may cause significant morbidity and mortality. Because sodium is the principal extracellular cation and it is restricted to the ECF, adequate body sodium is necessary for maintenance of intravascular volume. The principal extracellular anion, chloride, is also necessary, but for simplicity, sodium balance is considered the main regulator of volume status because body content of sodium and that of chloride usually change proportionally, given the need for equal numbers of cations and anions. In some situations, chloride depletion is considered the dominant derangement causing volume depletion (metabolic alkalosis with volume depletion). In other situations, such as volume depletion with metabolic acidosis, sodium depletion may exceed chloride depletion.

The kidney determines sodium balance because there is little homeostatic control of sodium intake, even though salt craving does occasionally occur, typically in children with chronic renal salt loss. The kidney regulates sodium balance by altering the percentage of filtered sodium that is resorbed along the nephron. Normally, the kidney excretes <1% of the sodium filtered at the glomerulus. In the absence of disease, extrarenal losses and urinary output match intake, with the kidney having the capacity to adapt to large variations in sodium intake. When necessary, urinary sodium excretion can be reduced to virtually undetectable levels or increased dramatically.

Urinary sodium excretion is regulated by both intrarenal and extrarenal mechanisms. The most important determinant of renal sodium excretion is the volume status of the child; it is the effective intravascular volume that influences urinary sodium excretion. The effective intravascular volume is the volume status that is sensed by the body's regulatory mechanisms. Heart failure is a state of volume overload, but the effective intravascular volume is low because poor cardiac function prevents adequate perfusion of the kidneys and other organs. This fact explains the avid renal sodium retention that is often present in patients with heart failure.

Sodium resorption occurs throughout the nephron. Whereas the majority of filtered sodium is resorbed in the proximal tubule and the loop of Henle, the distal tubule and the collecting duct are the main sites for precise regulation of sodium balance. Approximately 65% of the filtered sodium is reclaimed in the proximal tubule, which is the major site for resorption of bicarbonate, glucose, phosphate, amino acids, and other substances that are filtered by the glomerulus. The transport of all these substances is linked to sodium resorption by cotransporters, or a sodium-hydrogen exchanger in the case of bicarbonate. This link is clinically important for bicarbonate and phosphate because their resorption parallels sodium resorption. In patients with **metabolic alkalosis and volume depletion**, correction of the metabolic alkalosis requires urinary loss of bicarbonate, but the volume depletion stimulates sodium and bicarbonate retention, preventing correction of the alkalosis. Volume expansion causes increased urinary losses of phosphate, even when there is phosphate depletion. Resorption of uric acid and urea occurs in the proximal tubule and increases when sodium retention increases. This arrangement accounts for the elevated uric acid and BUN measurements that often accompany dehydration, which is a stimulus for sodium retention in the proximal tubule. The cells of the proximal tubule are permeable to water; thus, water resorption in this segment parallels sodium resorption.

The loop of Henle is, in terms of absolute amount, the second most important site of sodium resorption along the nephron. The Na^+,K^+,$2Cl^-$ cotransporter on the luminal side of the membrane reclaims filtered sodium and chloride, whereas most of the potassium is recycled back into the lumen. This is the transporter that is inhibited by furosemide and other loop diuretics, which are highly effective at increasing sodium excretion. The ascending limb of the loop of Henle is not permeable to water, permitting sodium retention without water. ADH stimulates sodium retention in this segment; this arrangement helps create a more hypertonic medulla, which maximizes water conservation when ADH acts in the medullary collecting duct. Because loop diuretics inhibit sodium retention in this segment, their use causes a less hypertonic medulla, preventing excretion of maximally concentrated urine in the presence of ADH.

Sodium retention in the distal tubule is mediated by the thiazide-sensitive Na^+,Cl^- cotransporter. This segment of the nephron is relatively impermeable to water, and along with sodium and chloride retention, the distal tubule is important for delivery of fluid with a low sodium concentration to the collecting duct. This allows for excretion of water without sodium in patients who stop secreting ADH because of low plasma osmolality. Thiazide diuretics, by inhibiting sodium and chloride retention in this segment, prevent the excretion of water without electrolytes—partially explaining the severe hyponatremia that occasionally develops in patients receiving chronic thiazide diuretics.

The collecting duct, the final segment of the nephron, is important for the regulation of excretion of water, potassium, acid, and sodium. Even though the amount of sodium resorbed in this segment is less than in any other segment, this is the critical site for the regulation of sodium balance. Sodium resorption occurs via a sodium channel that is regulated by aldosterone. When these channels are open under the influence of aldosterone, almost all of the sodium can be resorbed. The uptake of sodium creates a negative charge in the lumen of the collecting duct, which facilitates the secretion of potassium and hydrogen ions. The potassium-sparing diuretics amiloride and triamterene block these sodium channels, and the inhibition of sodium uptake decreases potassium excretion. The potassium-sparing diuretic spironolactone blocks the binding of aldosterone to its receptor; thus, it indirectly decreases the activity of the sodium channels. The collecting duct is important for the regulation of water balance because it responds to ADH by inserting water channels that increase the permeability to water, and the hypertonicity of the renal medulla allows for maximal concentration of the urine.

The amount of sodium filtered at the glomerulus is directly proportional to the GFR. If sodium resorption in the nephron were constant, complete resorption of sodium with a small decrease in the GFR and significant renal sodium wasting with a small increase would result. This does not occur, however, because sodium resorption in the nephron is proportional to sodium delivery, a principle called **glomerular tubular balance.**

The **renin–angiotensin system** is an important regulator of renal sodium excretion. The juxtaglomerular apparatus produces renin in

response to decreased effective intravascular volume. Specific stimuli for renin release are decreased perfusion pressure in the afferent arteriole of the glomerulus, decreased delivery of sodium to the distal nephron, and β_1-adrenergic agonists, which increase in response to intravascular volume depletion. Renin, a proteolytic enzyme, cleaves angiotensinogen, producing angiotensin I. Angiotensin-converting enzyme converts angiotensin I into angiotensin II. The actions of angiotensin II include direct stimulation of the proximal tubule to increase sodium resorption and stimulation of the adrenal gland to increase aldosterone secretion. Through its actions in the distal nephron—specifically, the late distal convoluted tubule and the collecting duct—aldosterone increases sodium resorption. Aldosterone also stimulates potassium excretion, increasing urinary losses. Along with decreasing urinary loss of sodium, angiotensin II acts as a vasoconstrictor, which helps maintain adequate blood pressure in the presence of volume depletion.

Volume expansion stimulates the synthesis of atrial natriuretic peptide, which is produced by the atria in response to atrial wall distention. Along with increasing the GFR, atrial natriuretic peptide inhibits sodium resorption in the medullary portion of the collecting duct, facilitating an increase in urinary sodium excretion.

Volume overload occurs when sodium intake exceeds output. In children with kidney failure, there is an impaired ability to excrete sodium. This impairment tends to be proportional to the decrease in the GFR, although in some kidney diseases, such as renal dysplasia and juvenile nephronophthisis, damaged tubules cause significant sodium loss until the GFR is quite low. In general, as the GFR decreases, restriction of sodium intake becomes increasingly necessary. The GFR is low at birth, limiting a newborn's ability to excrete a sodium load. In other situations, there is a loss of the appropriate regulation of renal sodium excretion. This loss occurs in patients with excessive aldosterone, as is seen in primary hyperaldosteronism or renal artery stenosis, wherein excess renin production leads to high aldosterone levels. In acute glomerulonephritis, even without significantly reduced GFR, the normal intrarenal mechanisms that regulate sodium excretion malfunction, causing excessive renal retention of sodium and volume overload.

Renal retention of sodium occurs during volume depletion, but this appropriate response causes the severe excess in total body sodium that is present in heart failure, liver failure, nephrotic syndrome, and other causes of hypoalbuminemia. In these diseases, the effective intravascular volume is decreased, causing the kidney and the various regulatory systems to respond, leading to renal sodium retention and edema formation.

Volume depletion usually occurs when sodium losses exceed intake. The most common etiology in children is gastroenteritis. Excessive losses of sodium may also occur from the skin in children with burns, in sweat from patients with cystic fibrosis, or after vigorous exercise. Inadequate intake of sodium is uncommon except in neglect, in famine, or with an inappropriate choice of liquid diet in a child who cannot take solids. Urinary sodium wasting may occur in a range of renal diseases, from renal dysplasia to tubular disorders, such as Bartter syndrome. The neonate, especially if premature, has a mild impairment in the ability to conserve sodium. Iatrogenic renal sodium wasting takes place during diuretic therapy. Renal sodium loss occurs as a result of derangement in the normal regulatory systems. An absence of aldosterone, seen most commonly in children with **congenital adrenal hyperplasia** caused by 21-hydroxylase deficiency, causes sodium wasting (see Chapter 576).

Isolated disorders of water balance can affect volume status and sodium balance. Because the cell membrane is permeable to water, changes in TBW influence both the extracellular volume and the intracellular volume. In isolated water loss, as occurs in diabetes insipidus, the impact is greater on the intracellular space because of its higher volume compared with the extracellular space. This is why, in comparison with other types of dehydration, hypernatremic dehydration has less impact on plasma volume; most of the fluid loss comes from the intracellular space. Yet, significant water loss eventually affects intravascular volume and will stimulate renal sodium retention, even if total body sodium content is normal. Similarly, with acute water intoxication or SIADH, there is an excess of TBW, but most is in the intracellular space. However, there is some effect on the intravascular volume, which causes renal excretion of sodium. Children with SIADH or water intoxication have high urine sodium concentrations, despite hyponatremia. This finding reinforces the concept that there are independent control systems for water and sodium, yet the 2 systems interact when pathophysiologic processes dictate, and control of effective intravascular volume always takes precedence over control of osmolality.

55.3 Sodium

Larry A. Greenbaum

SODIUM METABOLISM

Body Content and Physiologic Function

Sodium is the dominant cation of the ECF (see Fig. 55-3), and it is the principal determinant of extracellular osmolality. Sodium is therefore necessary for the maintenance of intravascular volume. Less than 3% of sodium is intracellular. More than 40% of total body sodium is in bone; the remainder is in the interstitial and intravascular spaces. The low intracellular sodium concentration, approximately 10 mEq/L, is maintained by Na^+,K^+-ATPase, which exchanges intracellular sodium for extracellular potassium.

Intake

A child's diet determines the amount of sodium ingested—a predominantly cultural determination in older children. An occasional child has salt craving because of an underlying salt-wasting renal disease or adrenal insufficiency. Children in the United States tend to have very high sodium intakes because their diets include a large amount of "junk" food or fast food. Infants receive sodium from breast milk (≈7 mEq/L) and formula (7-13 mEq/L, for 20 calorie/oz formula).

Sodium is readily absorbed throughout the gastrointestinal tract. Mineralocorticoids increase sodium transport into the body, although this effect has limited clinical significance. The presence of glucose enhances sodium absorption owing to the presence of a cotransport system. This is the rationale for including sodium and glucose in oral rehydration solutions (see Chapter 340).

Excretion

Sodium excretion occurs in stool and sweat, but the kidney regulates sodium balance and is the principal site of sodium excretion. There is some sodium loss in stool, but it is minimal unless diarrhea is present. Normally, sweat has 5-40 mEq/L of sodium. Sweat sodium concentration is increased in children with cystic fibrosis, aldosterone deficiency, or pseudohypoaldosteronism. The higher sweat losses in these conditions may cause or contribute to sodium depletion.

Sodium is unique among electrolytes because water balance, not sodium balance, usually determines its concentration. When the sodium concentration increases, the resultant higher plasma osmolality causes increased thirst and increased secretion of ADH, which leads to renal conservation of water. Both of these mechanisms increase the water content of the body, and the sodium concentration returns to normal. During hyponatremia, the decrease in plasma osmolality stops ADH secretion, and consequent renal water excretion leads to an increase in the sodium concentration. Even though water balance is usually regulated by osmolality, volume depletion does stimulate thirst, ADH secretion, and renal conservation of water. Volume depletion takes precedence over osmolality; volume depletion stimulates ADH secretion, even if a patient has hyponatremia.

The excretion of sodium by the kidney is not regulated by the plasma osmolality. The patient's effective plasma volume determines the amount of sodium in the urine. This is mediated by a variety of regulatory systems, including the renin–angiotensin–aldosterone system and

intrarenal mechanisms. In hyponatremia or hypernatremia, the underlying pathophysiology determines the amount of urinary sodium, not the serum sodium concentration.

HYPERNATREMIA

Hypernatremia is a sodium concentration >145 mEq/L, although it is sometimes defined as >150 mEq/L. Mild hypernatremia is fairly common in children, especially among infants with gastroenteritis. Hypernatremia in hospitalized patients may be iatrogenic—caused by inadequate water administration or, less often, by excessive sodium administration. Moderate or severe hypernatremia has significant morbidity, including the result of underlying disease, the effects of hypernatremia on the brain, and the risks of overly rapid correction.

Etiology and Pathophysiology

There are 3 basic mechanisms of hypernatremia (Table 55-1). Sodium intoxication is frequently iatrogenic in a hospital setting as a result of correction of metabolic acidosis with sodium bicarbonate. Baking soda, a putative home remedy for upset stomach, is another source of sodium bicarbonate; the hypernatremia is accompanied by a profound metabolic alkalosis. In hyperaldosteronism, there is renal retention of sodium and resultant hypertension; hypernatremia may not be present or is usually mild.

Table 55-1 Causes of Hypernatremia
EXCESSIVE SODIUM
Improperly mixed formula
Excess sodium bicarbonate
Ingestion of seawater or sodium chloride
Intentional salt poisoning (child abuse or Munchausen syndrome by proxy)
Intravenous hypertonic saline
Hyperaldosteronism
WATER DEFICIT
Nephrogenic diabetes insipidus
Acquired
X-linked (OMIM 304800)
Autosomal recessive (OMIM 222000)
Autosomal dominant (OMIM 125800)
Central diabetes insipidus
Acquired
Autosomal recessive (OMIM 125700)
Autosomal dominant (OMIM 125700)
Wolfram syndrome (OMIM 222300/598500)
Increased insensible losses
Premature infants
Radiant warmers
Phototherapy
Inadequate intake:
Ineffective breastfeeding
Child neglect or abuse
Adipsia (lack of thirst)
WATER AND SODIUM DEFICITS
Gastrointestinal losses
Diarrhea
Emesis/nasogastric suction
Osmotic cathartics (lactulose)
Cutaneous losses
Burns
Excessive sweating
Renal losses
Osmotic diuretics (mannitol)
Diabetes mellitus
Chronic kidney disease (dysplasia and obstructive uropathy)
Polyuric phase of acute tubular necrosis
Postobstructive diuresis

OMIM, database number from the Online Mendelian Inheritance in Man (http://www.ncbi.nlm.nih.gov/omim).

The classic causes of hypernatremia from a water deficit are **nephrogenic** and **central diabetes insipidus** (see Chapters 530 and 558). Hypernatremia develops in diabetes insipidus only if the patient does not have access to water or cannot drink adequately because of immaturity, neurologic impairment, emesis, or anorexia. Infants are at high risk because of their inability to control their own water intake. Central diabetes insipidus and the genetic forms of nephrogenic diabetes insipidus typically cause massive urinary water losses and very dilute urine. The water losses are less dramatic, and the urine often has the same osmolality as plasma when nephrogenic diabetes insipidus is secondary to intrinsic renal disease (obstructive uropathy, renal dysplasia, sickle cell disease).

The other causes of a water deficit are also secondary to an imbalance between losses and intake. Newborns, especially if premature, have high insensible water losses. Losses are further increased if the infant is placed under a radiant warmer or with the use of phototherapy for hyperbilirubinemia. The renal concentrating mechanisms are not optimal at birth, providing an additional source of water loss. Ineffective breastfeeding, often in a primiparous mother, can cause severe hypernatremic dehydration. Adipsia, the absence of thirst, is usually secondary to damage to the hypothalamus, such as from trauma, tumor, hydrocephalus, or histiocytosis. Primary adipsia is rare.

When hypernatremia occurs in conditions with deficits of sodium and water, the water deficit exceeds the sodium deficit. This occurs only if the patient is unable to ingest adequate water. Diarrhea results in depletion of both sodium and water. Because diarrhea is hypotonic—typical sodium concentration of 35-65 mEq/L—water losses exceed sodium losses, potentially leading to hypernatremia. Most children with gastroenteritis do not have hypernatremia because they drink enough hypotonic fluid to compensate for stool water losses (see Chapter 340). Fluids such as water, juice, and formula are more hypotonic than the stool losses, allowing correction of the water deficit and potentially even causing hyponatremia. Hypernatremia is most likely to occur in the child with diarrhea who has inadequate intake because of emesis, lack of access to water, or anorexia.

Osmotic agents, including mannitol and glucose in diabetes mellitus, cause excessive renal losses of water and sodium. Because the urine is hypotonic (sodium concentration of approximately 50 mEq/L) during an osmotic diuresis, water loss exceeds sodium loss and hypernatremia may occur if water intake is inadequate. Certain chronic kidney diseases, such as renal dysplasia and obstructive uropathy, are associated with tubular dysfunction, leading to excessive losses of water and sodium. Many children with such diseases have disproportionate water loss and are at risk for hypernatremic dehydration, especially if gastroenteritis supervenes. Similar mechanisms occur during the polyuric phase of acute tubular necrosis and after relief of urinary obstruction (postobstructive diuresis). Patients with either condition may have an osmotic diuresis from urinary losses of urea and an inability to conserve water because of tubular dysfunction.

Clinical Manifestations

Most children with hypernatremia are dehydrated and show the typical clinical signs and symptoms (see Chapter 57). Children with hypernatremic dehydration tend to have better preservation of intravascular volume because of the shift of water from the intracellular space to the extracellular space. This shift maintains blood pressure and urine output and allows hypernatremic infants to be less symptomatic initially and potentially to become more dehydrated before medical attention is sought. Breastfed infants with hypernatremia are often profoundly dehydrated, with failure to thrive. Probably because of intracellular water loss, the pinched abdominal skin of a dehydrated, hypernatremic infant has a "doughy" feel.

Hypernatremia, even without dehydration, causes central nervous system (CNS) symptoms that tend to parallel the degree of sodium elevation and the acuity of the increase. Patients are irritable, restless, weak, and lethargic. Some infants have a high-pitched cry and hyperpnea. Alert patients are very thirsty, even though nausea may be present. Hypernatremia may cause fever, although many patients have

an underlying process that contributes to the fever. Hypernatremia is associated with hyperglycemia and mild hypocalcemia; the mechanisms are unknown. Beyond the sequelae of dehydration, there is no clear direct effect of hypernatremia on other organs or tissues, except the brain.

Brain hemorrhage is the most devastating consequence of untreated hypernatremia. As the extracellular osmolality increases, water moves out of brain cells, leading to a decrease in brain volume. This decrease can result in tearing of intracerebral veins and bridging blood vessels as the brain moves away from the skull and the meninges. Patients may have subarachnoid, subdural, and parenchymal hemorrhages. Seizures and coma are possible sequelae of the hemorrhage, although seizures are more common during correction of hypernatremia. The cerebrospinal fluid protein is often elevated in infants with significant hypernatremia, probably owing to leakage from damaged blood vessels. Neonates, especially if premature, seem especially vulnerable to hypernatremia and excessive sodium intake. There is an association between rapid or hyperosmolar sodium bicarbonate administration and the development of intraventricular hemorrhages in neonates. Even though central pontine myelinolysis (CPM) is classically associated with overly rapid correction of hyponatremia, both CPM and extrapontine myelinolysis can occur in children with hypernatremia. Thrombotic complications occur in severe hypernatremic dehydration; they include stroke, dural sinus thrombosis, peripheral thrombosis, and renal vein thrombosis. This is secondary to dehydration and possibly hypercoagulability associated with hypernatremia.

Diagnosis

The etiology of hypernatremia is usually apparent from the history. Hypernatremia resulting from water loss occurs only if the patient does not have access to water or is unable to drink. In the absence of dehydration, it is important to ask about sodium intake. Children with excess sodium intake do not have signs of dehydration, unless another process is present. Severe sodium intoxication causes signs of volume overload, such as pulmonary edema and weight gain. **Salt poisoning** is associated with an elevated fractional excretion of sodium, whereas hypernatremic dehydration causes a low fractional excretion of sodium. In hyperaldosteronism, hypernatremia is usually mild or absent and is associated with edema, hypertension, hypokalemia, and metabolic alkalosis.

When there is isolated water loss, the signs of volume depletion are usually less severe initially because much of the loss is from the intracellular space. When pure water loss causes signs of dehydration, the hypernatremia and water deficit are usually severe. In the child with renal water loss, either central or nephrogenic diabetes insipidus, the urine is inappropriately dilute and urine volume is not low. The urine is maximally concentrated and urine volume is low if the losses are extrarenal or due to inadequate intake. With extrarenal causes of loss of water, the urine osmolality should be >1,000 mOsm/kg. When diabetes insipidus is suspected, the evaluation may include measurement of ADH and a water deprivation test, including a trial of desmopressin acetate (synthetic ADH analog) to differentiate between nephrogenic diabetes insipidus and central diabetes insipidus (see Chapters 530 and 558). A water-deprivation test is unnecessary if the patient has simultaneous documentation of hypernatremia and poorly concentrated urine (osmolality lower than that of plasma). In children with central diabetes insipidus, administration of desmopressin acetate increases the urine osmolality above the plasma osmolality, although maximum osmolality does not occur immediately because of the decreased osmolality of the renal medulla as a result of the chronic lack of ADH. In children with nephrogenic diabetes insipidus, there is no response to desmopressin acetate.

With combined sodium and water deficits, analysis of the urine differentiates between renal and nonrenal etiologies. When the losses are extrarenal, the kidney responds to volume depletion with low urine volume, concentrated urine, and sodium retention (urine sodium <20 mEq/L, fractional excretion of sodium <1%). With renal causes, the urine volume is not appropriately low, the urine is not maximally concentrated, and the urine sodium may be inappropriately elevated.

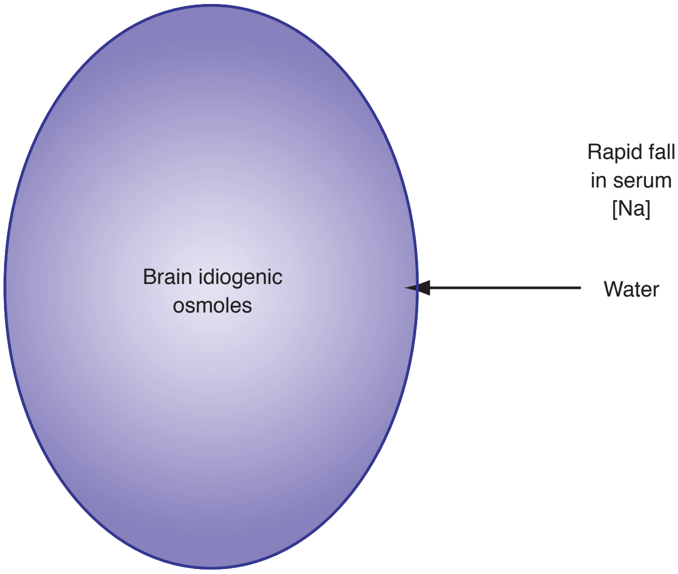

Figure 55-4 **Mechanism of brain edema during correction of hypernatremia.** A rapid decrease of the serum concentration during treatment of hypernatremia causes movement of water into brain cells, leading to cerebral edema. The presence of idiogenic osmoles in brain cells is responsible for the osmotic gradient.

Treatment

As hypernatremia develops, the brain generates **idiogenic osmoles** to increase the intracellular osmolality and prevent the loss of brain water. This mechanism is not instantaneous and is most prominent when hypernatremia has developed gradually. If the serum sodium concentration is lowered rapidly, there is movement of water from the serum into the brain cells to equalize the osmolality in the 2 compartments (Fig. 55-4). The resultant brain swelling manifests as seizures or coma.

Because of the associated dangers, hypernatremia should not be corrected rapidly. The goal is to decrease the serum sodium by <12 mEq/L every 24 hr, a rate of 0.5 mEq/L/hr. The most important component of correcting moderate or severe hypernatremia is frequent monitoring of the serum sodium value so that fluid therapy can be adjusted to provide adequate correction, neither too slow nor too fast. If a child has seizures as a result of brain edema secondary to rapid correction, administration of hypotonic fluid should be stopped. An infusion of 3% saline can acutely increase the serum sodium, reversing the cerebral edema.

In the child with hypernatremic dehydration, as in any child with dehydration, the **first priority is restoration of intravascular volume** with isotonic fluid (see Chapter 57). Normal saline is preferable to lactated Ringer solution because the lower sodium concentration of the latter can cause the serum sodium to decrease too rapidly, especially if multiple fluid boluses are given. Repeated boluses of normal saline (10-20 mL/kg) may be required to treat hypotension, tachycardia, and signs of poor perfusion (peripheral pulses, capillary refill time) (see Chapters 57 and 70).

The sodium concentration of the deficit replacement fluid, the rate of fluid administration, and the presence of continued water losses determine the rate of decrease of the sodium concentration. The following formula is often cited for calculating the water deficit:

$$\text{Water deficit} = \text{Body weight} \times 0.6(1\text{-}145)/[\text{current sodium}])$$

This calculation is equivalent to 3-4 mL of water per kg for each 1 mEq that the current sodium level exceeds 145 mEq. The utility of such formulas has never been proven in clinical practice. Most patients with hypernatremic dehydration do well with a fluid sodium concentration of approximately half-normal saline, but with a fluid rate that is only 20-30% greater than maintenance fluid. Use of this

concentration prevents excessive delivery of free water and too rapid a decrease in the serum sodium level. Patients with pure water loss may require a more hypotonic fluid (0.2 normal saline). Excessive water and sodium losses may also need to be replaced. If signs or symptoms of volume depletion develop, the patient receives additional boluses of isotonic saline. Monitoring of the rate of decrease of the serum sodium concentration permits adjustment in the rate and sodium concentration of the fluid that the patient is receiving, avoiding overly rapid correction of the hypernatremia (see Chapter 57 for additional details). Many patients with mild to moderate hypernatremic dehydration as a result of gastroenteritis can be managed with oral rehydration (see Chapter 340).

Acute, severe hypernatremia, usually secondary to sodium administration, can be corrected more rapidly because idiogenic osmoles have not had time to accumulate. This fact balances the high morbidity and mortality rates associated with hypernatremia with the dangers of overly rapid correction. When hypernatremia is severe and is caused by sodium intoxication, it may be impossible to administer enough water to correct the hypernatremia rapidly without worsening the volume overload. In this situation, dialysis allows for removal of the excess sodium, with the precise strategy dependent on the mode of dialysis. In less-severe cases, the addition of a loop diuretic increases the removal of excess sodium and water, decreasing the risk of volume overload. With sodium overload, hypernatremia is corrected with sodium-free intravenous fluid (5% dextrose in water).

Hyperglycemia from hypernatremia is not usually a problem and is not treated with insulin because the acute decrease in glucose may precipitate cerebral edema by lowering plasma osmolality. Rarely, the glucose concentration of intravenous fluids must be reduced (from 5% dextrose in water to 2.5% dextrose in water). The secondary hypocalcemia is treated as needed.

It is important to address the underlying cause of the hypernatremia, if possible. The child with central diabetes insipidus should receive desmopressin acetate. Because this treatment reduces renal excretion of water, excessive intake of water must consequently be avoided to prevent both overly rapid correction of the hypernatremia and the development of hyponatremia. Over the long-term, reduced sodium intake and the use of medications can somewhat ameliorate the water losses in nephrogenic diabetes insipidus (see Chapter 530). The daily water intake of a child who is receiving tube feeding may need to be increased to compensate for high losses. The patient with significant ongoing losses, such as through diarrhea, may need supplemental water and electrolytes (see Chapter 56). Sodium intake is reduced if it contributed to the hypernatremia.

HYPONATREMIA

Hyponatremia, a very common electrolyte abnormality in hospitalized patients, is a serum sodium level <135 mEq/L. Both total body sodium and TBW determine the serum sodium concentration. Hyponatremia exists when the ratio of water to sodium is increased. This condition can occur with low, normal, or high levels of body sodium. Similarly, body water can be low, normal, or high.

Etiology and Pathophysiology

Table 55-2 lists the causes of hyponatremia. Pseudohyponatremia is a laboratory artifact that is present when the plasma contains very high concentrations of protein (multiple myeloma, intravenous immunoglobulin infusion) or lipid (hypertriglyceridemia, hypercholesterolemia). It does not occur when a direct ion-selective electrode determines the sodium concentration in undiluted plasma, a technique that is used by arterial blood gas analyzers or point-of-care instruments. In true hyponatremia, the measured osmolality is low, whereas it is normal in pseudohyponatremia. Hyperosmolality, as may occur with hyperglycemia, causes a low serum sodium concentration because water moves down its osmotic gradient from the intracellular space into the extracellular space, diluting the sodium concentration. However, because the manifestations of hyponatremia are a result of the low plasma osmolality, patients with hyponatremia resulting from hyperosmolality do not have symptoms of hyponatremia. When the etiology of the hyperosmolality resolves, such as hyperglycemia in diabetes mellitus, water moves back into the cells and the sodium concentration rises to its "true" value. Mannitol or sucrose, a component of intravenous immunoglobulin preparations, may cause hyponatremia because of hyperosmolality.

Classification of hyponatremia is based on the patient's volume status. In **hypovolemic hyponatremia,** the child has lost sodium from the body. The water balance may be positive or negative, but sodium loss has been higher than water loss. The pathogenesis of the

*Most cases of proximal renal tubular acidosis are not caused by this primary genetic disorder. Proximal renal tubular acidosis is usually part of Fanconi syndrome, which has multiple etiologies.

OMIM, database number from the Online Mendelian Inheritance in Man (http://www.ncbi.nlm.nih.gov/omim).

hyponatremia is usually a combination of sodium loss and water retention to compensate for the volume depletion. The patient has a pathologic increase in fluid loss, and this fluid contains sodium. Most fluid that is lost has a lower sodium concentration than that of plasma. Viral diarrhea fluid has, on average, a sodium concentration of 50 mEq/L. Replacing diarrhea fluid, which has a sodium concentration of 50 mEq/L, with formula, which has only approximately 10 mEq/L of sodium, reduces the sodium concentration. Intravascular volume depletion interferes with renal water excretion, the body's usual mechanism for preventing hyponatremia. The volume depletion stimulates ADH synthesis, resulting in renal water retention. Volume depletion also decreases the GFR and enhances water resorption in the proximal tubule, thereby reducing water delivery to the collecting duct.

Diarrhea as a result of gastroenteritis is the most common cause of **hypovolemic hyponatremia** in children. Emesis causes hyponatremia if the patient takes in hypotonic fluid, either intravenously or enterally, despite the emesis. Most patients with emesis have either a normal sodium concentration or hypernatremia. Burns may cause massive losses of isotonic fluid and resultant volume depletion. Hyponatremia develops if the patient receives hypotonic fluid. Losses of sodium from sweat are especially high in children with cystic fibrosis, aldosterone deficiency, or pseudohypoaldosteronism, although high losses can occur simply in a hot climate. Third-space losses are isotonic and can cause significant volume depletion, leading to ADH production and water retention, which can cause hyponatremia if the patient receives hypotonic fluid. In diseases that cause volume depletion through extrarenal sodium loss, the urine sodium level should be low (<10 mEq/L) as part of the renal response to maintain the intravascular volume. The only exceptions are diseases that cause both extrarenal and renal sodium losses: adrenal insufficiency and pseudohypoaldosteronism.

Renal sodium loss may occur in a variety of situations. In some situations, the urine sodium concentration is >140 mEq/L; thus, hyponatremia may occur without any fluid intake. In many cases, the urine sodium level is less than the serum concentration; thus, the intake of hypotonic fluid is necessary for hyponatremia to develop. In diseases associated with urinary sodium loss, the urine sodium level is >20 mEq/L despite volume depletion. This may not be true if the urinary sodium loss is no longer occurring, as is frequently the case if diuretics are discontinued. Because loop diuretics prevent generation of a maximally hypertonic renal medulla, the patient can neither maximally dilute nor concentrate the urine. The inability to maximally retain water provides some protection against severe hyponatremia. The patient receiving thiazide diuretics can concentrate the urine and is at higher risk for severe hyponatremia. Osmotic agents, such as glucose during diabetic ketoacidosis, cause loss of both water and sodium. Urea accumulates during renal failure and then acts as an osmotic diuretic after relief of urinary tract obstruction and during the polyuric phase of acute tubular necrosis. Transient tubular damage in these conditions further impairs sodium conservation. The serum sodium concentration in these conditions depends on the sodium concentration of the fluid used to replace the losses. Hyponatremia develops when the fluid is hypotonic relative to the urinary losses.

Renal salt wasting occurs in hereditary kidney diseases, such as juvenile nephronophthisis and autosomal recessive polycystic kidney disease. Obstructive uropathy, most commonly a consequence of posterior urethral valves, produces salt wasting, but patients with the disease may also have hypernatremia as a result of impaired ability to concentrate urine and high water loss. Acquired tubulointerstitial nephritis, usually secondary to either medications or infections, may cause salt wasting, along with other evidence of tubular dysfunction. CNS injury may produce cerebral salt wasting, which is theoretically caused by the production of a natriuretic peptide that causes renal salt wasting. In type II renal tubular acidosis (RTA), usually associated with Fanconi syndrome (see Chapter 529.1), there is increased excretion of sodium and bicarbonate in the urine. Patients with Fanconi syndrome also have glycosuria, aminoaciduria, and hypophosphatemia because of renal phosphate wasting.

Aldosterone is necessary for renal sodium retention and for the excretion of potassium and acid. In congenital adrenal hyperplasia caused by 21-hydroxylase deficiency, the block of aldosterone production results in hyponatremia, hyperkalemia, and metabolic acidosis. In pseudohypoaldosteronism, aldosterone levels are elevated, but there is no response because of either a defective sodium channel or a deficiency of aldosterone receptors. A lack of tubular response to aldosterone may occur in children with urinary tract obstruction, especially during an acute urinary tract infection.

In **hypervolemic hyponatremia,** there is an excess of TBW and sodium, although the increase in water is greater than the increase in sodium. In most of the conditions that cause hypervolemic hyponatremia, there is a decrease in the effective blood volume, resulting from third space fluid loss, vasodilation, or poor cardiac output. The regulatory systems sense a decrease in effective blood volume and attempt to retain water and sodium to correct the problem. ADH causes renal water retention, and the kidney, under the influence of aldosterone and other intrarenal mechanisms, retains sodium. The patient's sodium concentration decreases because water intake exceeds sodium intake and ADH prevents the normal loss of excess water.

In these disorders, there is a low urine sodium concentration (<10 mEq/L) and an excess of both TBW and sodium. The only exception is in patients with renal failure and hyponatremia. These patients have an expanded intravascular volume, and hyponatremia can therefore appropriately suppress ADH production. Water cannot be excreted because very little urine is being made. Serum sodium is diluted through ingestion of water. Because of renal dysfunction, the urine sodium concentration may be elevated, but urine volume is so low that urine sodium excretion has not kept up with sodium intake, leading to sodium overload. The urine sodium concentration in renal failure varies. In patients with acute glomerulonephritis, because it does not affect the tubules, the urine sodium level is usually low, whereas in patients with acute tubular necrosis, it is elevated because of tubular dysfunction.

Patients with hyponatremia and no evidence of volume overload or volume depletion have **euvolemic hyponatremia.** These patients typically have an excess of TBW and a slight decrease in total body sodium. Some of these patients have an increase in weight, implying that they are volume-overloaded. Nevertheless, from a clinical standpoint, they usually appear normal or have subtle signs of fluid overload.

In SIADH, the secretion of ADH is not inhibited by either low serum osmolality or expanded intravascular volume (see Chapter 559). The result is that the child with SIADH is unable to excrete water. This results in dilution of the serum sodium and hyponatremia. The expansion of the extracellular volume as a result of the retained water causes a mild increase in intravascular volume. The kidney increases sodium excretion in an effort to decrease intravascular volume to normal; thus, the patient has a mild decrease in body sodium. SIADH most commonly occurs with disorders of the CNS (infection, hemorrhage, trauma, tumor, thrombosis), but lung disease (infection, asthma, positive pressure ventilation) and malignant tumors (producing ADH) are other potential causes. A variety of medications may cause SIADH, including recreational use of 3,4-methylenedioxymethylamphetamine (MDMA, or "Ecstasy"), opiates, antiepileptic drugs (carbamazepine, oxcarbazepine, valproate), tricyclic antidepressants, vincristine, Cytoxan, and selective serotonin reuptake inhibitors. The diagnosis of SIADH is one of exclusion, because other causes of hyponatremia must be eliminated (Table 55-3). Because SIADH is a state of intravascular volume expansion, low serum uric acid and BUN levels are supportive of the diagnosis.

A rare gain-of-function mutation in the renal ADH receptor causes **nephrogenic syndrome of inappropriate antidiuresis.** Patients with this X-linked disorder appear to have SIADH but have undetectable levels of ADH.

Hyponatremia in hospitalized patients is frequently caused by inappropriate production of ADH and administration of hypotonic intravenous fluids. Causes of inappropriate ADH production include stress, medications such as narcotics or anesthetics, nausea, and respiratory illness. The synthetic analog of ADH, desmopressin acetate, causes

Table 55-3	Diagnostic Criteria for Syndrome of Inappropriate Antidiuretic Hormone Secretion
Absence of:	
Renal, adrenal, or thyroid insufficiency	
Heart failure, nephrotic syndrome, or cirrhosis	
Diuretic ingestion	
Dehydration	
Urine osmolality >100 mOsm/kg (usually > plasma)	
Serum osmolality <280 mOsm/kg and serum sodium <135 mEq/L	
Urine sodium >30 mEq/L	
Reversal of "sodium wasting" and correction of hyponatremia with water restriction	

water retention and may cause hyponatremia if fluid intake is not appropriately limited. The main uses of desmopressin acetate in children are for the management of central diabetes insipidus and of nocturnal enuresis.

Excess water ingestion can produce hyponatremia. In these cases, the sodium concentration decreases as a result of dilution. This decrease suppresses ADH secretion, and there is a marked water diuresis by the kidney. Hyponatremia develops only because the intake of water exceeds the kidney's ability to eliminate water. This condition is more likely to occur in infants because their lower GFR limits their ability to excrete water.

Hyponatremia may develop in infants <6 mo of age when caregivers offer water to their infant as a supplement, during hot weather, or when they run out of formula. Hyponatremia may result in transient seizures, hypothermia, and poor tone. With cessation of water intake, the hyponatremia rapidly corrects. Infants <6 mo of age should not be given water to drink; infants between 6 and 12 mo of age should not receive more than 1-2 ounces. If the infant appears thirsty, the parent should offer formula or breastfeed the child.

In some situations, the water intoxication causes acute hyponatremia and is a consequence of a massive acute water load. Examples of causes of this water load include infant swimming lessons, inappropriate use of hypotonic intravenous fluids, water enemas, and forced water intake as a form of child abuse. Chronic hyponatremia occurs in children who receive water, but limited sodium and protein. The minimum urine osmolality is approximately 50 mOsm/kg, the kidney can excrete 1 L of water only if there is enough solute ingested to produce 50 mOsm for urinary excretion. Because sodium and urea (a breakdown product of protein) are the principal urinary solutes, a lack of intake of sodium and protein prevents adequate water excretion. This occurs with the use of diluted formula or other inappropriate diets. Subsistence on beer, a poor source of sodium and protein, causes hyponatremia because of the inability to excrete the high water load ("beer potomania"). **Exercise-induced hyponatremia**, reported commonly during marathons, is caused by excessive water intake, salt losses from sweat, and secretion of ADH.

The pathogenesis of the hyponatremia in glucocorticoid deficiency is multifactorial, and includes increased ADH secretion. In hypothyroidism, there is an inappropriate retention of water by the kidney, but the precise mechanisms are not clearly elucidated.

Clinical Manifestations

Hyponatremia causes a decrease in the osmolality of the extracellular space. Because the intracellular space then has a higher osmolality, water moves from the extracellular space to the intracellular space to maintain osmotic equilibrium. The increase in intracellular water causes cells to swell. Although cell swelling is not problematic in most tissues, it is dangerous for the brain, which is confined by the skull. As brain cells swell, there is an increase in intracranial pressure, which impairs cerebral blood flow. Acute, severe hyponatremia can cause brainstem herniation and apnea; respiratory support is often necessary. Brain cell swelling is responsible for most of the symptoms of hyponatremia. Neurologic symptoms of hyponatremia include anorexia, nausea, emesis, malaise, lethargy, confusion, agitation, headache, seizures, coma, and decreased reflexes. Patients may have hypothermia and Cheyne-Stokes respirations. Hyponatremia can cause muscle cramps and weakness; rhabdomyolysis can occur with water intoxication.

The symptoms of hyponatremia are mostly a result of the decrease in extracellular osmolality and the resulting movement of water down its osmotic gradient into the intracellular space. Brain swelling can be significantly obviated if the hyponatremia develops gradually, because brain cells adapt to the decreased extracellular osmolality by reducing intracellular osmolality. This reduction is achieved by extrusion of the main intracellular ions (potassium and chloride) and a variety of small organic molecules. This process explains why the range of symptoms in hyponatremia is related to both the serum sodium level and its rate of decrease. A patient with chronic hyponatremia may have only subtle neurologic abnormalities with a serum sodium level of 110 mEq/L, but another patient may have seizures because of an acute decline in serum sodium level from 140 to 125 mEq/L.

Diagnosis

The history usually points to a likely etiology of the hyponatremia. Most patients with hyponatremia have a history of volume depletion. Diarrhea and diuretic use are very common causes of hyponatremia in children. A history of polyuria, perhaps with enuresis, and/or salt craving is present in children with primary kidney diseases or absence of aldosterone effect. Children may have signs or symptoms suggesting a diagnosis of hypothyroidism or adrenal insufficiency (see Chapters 565 and 575). Brain injury raises the possibility of SIADH or cerebral salt wasting, with the caveat that SIADH is much more likely. Liver disease, nephrotic syndrome, renal failure, or congestive heart failure may be acute or chronic. The history should include a review of the patient's intake, both intravenous and enteral, with careful attention to the amounts of water, sodium, and protein.

The traditional first step in the diagnostic process is determination of the plasma osmolality. This is done because some patients with a low serum sodium value do not have low osmolality. The clinical effects of hyponatremia are secondary to the associated low osmolality. Without a low osmolality, there is no movement of water into the intracellular space.

A patient with hyponatremia can have a low, normal, or high osmolality. A normal osmolality in combination with hyponatremia occurs in pseudohyponatremia. Children with elevation of serum glucose concentration or of another effective osmole (mannitol) have a high plasma osmolality and hyponatremia. The presence of a low osmolality indicates "true" hyponatremia. Patients with low osmolality are at risk for neurologic symptoms and require further evaluation to determine the etiology of the hyponatremia.

In some situations, true hyponatremia is present despite a normal or elevated plasma osmolality. The presence of an ineffective osmole, most commonly urea, increases the plasma osmolality, but because the osmole has the same concentration in the intracellular space, it does not cause fluid to move into the extracellular space. There is no dilution of the serum sodium by water, and the sodium concentration remains unchanged if the ineffective osmole is eliminated. Most importantly, the ineffective osmole does not protect the brain from edema caused by hyponatremia. Hence, a patient may have symptoms of hyponatremia despite having a normal or increased osmolality because of uremia.

In patients with true hyponatremia, the next step in the diagnostic process is to clinically evaluate the volume status. Patients with hyponatremia can be hypovolemic, hypervolemic, or euvolemic. The diagnosis of volume depletion relies on the usual findings with dehydration (see Chapter 57), although subtle volume depletion may not be clinically apparent. In a patient with subtle volume depletion, a fluid bolus results in a decrease in the urine osmolality and an increase in the serum sodium concentration. Children with hypervolemia are **edematous** on physical examination. They may have ascites, pulmonary edema, pleural effusion, or hypertension.

Hypovolemic hyponatremia can have renal or nonrenal causes. The urine sodium concentration is very useful in differentiating between renal and nonrenal causes. When the losses are nonrenal and the kidney is working properly, there is renal retention of sodium, a normal homeostatic response to volume depletion. Thus, the urinary sodium concentration is low, typically <10 mEq/L, although sodium conservation in neonates is less avid. When the kidney is the cause of the sodium loss, the urine sodium concentration is >20 mEq/L, reflecting the defect in renal sodium retention. The interpretation of the urine sodium level is challenging with diuretic therapy because it is high when diuretics are being used but low after the diuretic effect is gone. This becomes an issue only when diuretic use is surreptitious. The urine sodium concentration is not useful if a metabolic alkalosis is present; the urine chloride concentration must be used instead (see Chapter 55.7).

Differentiating among the nonrenal causes of hypovolemic hyponatremia is usually facilitated by the history. Although the renal causes are more challenging to distinguish, a high serum potassium concentration is associated with disorders in which the sodium wasting is caused by absence of or ineffectiveness of aldosterone.

In the patient with hypervolemic hyponatremia, the urine sodium concentration is a helpful parameter. It is usually <10 mEq/L, except in the patient with renal failure.

Treatment

The management of hyponatremia is based on the pathophysiology of the specific etiology. The management of all causes requires judicious monitoring and avoidance of an overly quick normalization of the serum sodium concentration. A patient with severe symptoms (seizures), no matter the etiology, should be given a bolus of hypertonic saline to produce a small, rapid increase in serum sodium. Hypoxia worsens cerebral edema, and hyponatremia may cause hypoxia. Hence, pulse oximetry should be monitored, and hypoxia aggressively corrected.

With all causes of hyponatremia, it is important to avoid "overly rapid" correction. The reason is that rapid correction of hyponatremia may cause CPM. This syndrome, which occurs within several days of rapid correction of hyponatremia, produces neurologic symptoms, including confusion, agitation, flaccid or spastic quadriparesis, and death. There are usually characteristic pathologic and radiologic changes in the brain, especially in the pons, but extrapontine lesions are quite common and may cause additional symptoms. Despite severe symptoms, full recovery does occur in some patients.

CPM is more common in patients who are treated for chronic hyponatremia than in those treated for acute hyponatremia. Presumably, this difference is based on the adaptation of brain cells to the hyponatremia. The reduced intracellular osmolality that is an adaptive mechanism for chronic hyponatremia makes brain cells susceptible to dehydration during rapid correction of the hyponatremia, and this may be the mechanism of CPM. Even though CPM is rare in pediatric patients, it is advisable to avoid correcting the serum sodium concentration by >12 mEq/L/24 hr or >18 mEq/L/48 hr. Desmopressin is a potential option if the serum sodium level is increasing too rapidly. This guideline does not apply to acute hyponatremia, as may occur with water intoxication, because the hyponatremia is more often symptomatic and there has not been time for the adaptive decrease in brain osmolality to occur. The consequences of brain edema in acute hyponatremia exceed the small risk of CPM.

Patients with hyponatremia can have severe neurologic symptoms, such as seizures and coma. The seizures associated with hyponatremia generally are poorly responsive to anticonvulsants. The child with hyponatremia and severe symptoms needs to receive treatment that will quickly reduce cerebral edema. This goal is best accomplished by increasing the extracellular osmolality so that water moves down its osmolar gradient from the intracellular space to the extracellular space.

Intravenous hypertonic saline rapidly increases serum sodium, and the effect on serum osmolality leads to a decrease in brain edema. Each mL/kg of 3% sodium chloride increases the serum sodium by approximately 1 mEq/L. A child with active symptoms often improves after receiving 4-6 mL/kg of 3% sodium chloride.

The child with **hypovolemic hyponatremia** has a deficiency in sodium and may have a deficiency in water. The cornerstone of therapy is to replace the sodium deficit and any water deficit that is present. The first step in treating any dehydrated patient is to restore the intravascular volume with isotonic saline. Ultimately, complete restoration of intravascular volume suppresses ADH production, thereby permitting excretion of the excess water. Chapter 57 discusses the management of hyponatremic dehydration.

The management of **hypervolemic hyponatremia** is difficult. Patients with this disorder have an excess of both water and sodium. Administration of sodium leads to worsening volume overload and edema. In addition, the patients are retaining water and sodium because of their ineffective intravascular volume or renal insufficiency. The cornerstone of therapy is water and sodium restriction, because the patients have volume overload. Diuretics may help by causing excretion of both sodium and water. Vasopressin antagonists, by blocking the action of ADH and causing a water diuresis, are effective in correcting the hypervolemic hyponatremia caused by heart failure or cirrhosis.

Some patients with low albumin resulting from nephrotic syndrome have a better response to diuretics after an infusion of 25% albumin; the sodium concentration often normalizes as a result of expansion of the intravascular volume. A child with heart failure may have an increase in renal water and sodium excretion if there is an improvement in cardiac output. This improvement will "turn off" the regulatory hormones that are causing renal water (ADH) and sodium (aldosterone) retention. The patient with renal failure cannot respond to any of these therapies except fluid restriction. Insensible fluid losses eventually result in an increase in the sodium concentration as long as insensible and urinary losses are greater than intake. A more definitive approach in children with renal failure is to perform dialysis, which removes water and sodium.

In isovolumic hyponatremia, there is usually an excess of water and a mild sodium deficit. Therapy is directed at eliminating the excess water. The child with acute excessive water intake loses water in the urine because ADH production is turned off as a result of the low plasma osmolality. Children may correct their hyponatremia spontaneously over 3-6 hr. For acute, symptomatic hyponatremia as a result of water intoxication, hypertonic saline may be needed to reverse cerebral edema. For chronic hyponatremia from poor solute intake, the child needs to receive an appropriate formula, and excess water intake should be eliminated.

Children with iatrogenic hyponatremia caused by the administration of hypotonic intravenous fluids should receive 3% saline if they are symptomatic. Subsequent management is dictated by the patient's volume status. The hypovolemic child should receive isotonic intravenous fluids. The child with nonphysiologic stimuli for ADH production should undergo fluid restriction. Prevention of this iatrogenic complication requires judicious use of intravenous fluids (see Chapter 56).

Specific hormone replacement is the cornerstone of therapy for the hyponatremia of hypothyroidism or cortisol deficiency. Correction of the underlying defect permits appropriate elimination of the excess water.

SIADH is a condition of excess water, with limited ability of the kidney to excrete water. The mainstay of its therapy is fluid restriction. Furosemide is effective in the patient with SIADH and severe hyponatremia. Even in a patient with SIADH, furosemide causes an increase in water and sodium excretion. The loss of sodium is somewhat counterproductive, but this sodium can be replaced with hypertonic saline. Because the patient has a net loss of water and the urinary losses of sodium have been replaced, there is an increase in the sodium concentration, but no significant increase in blood pressure. Vasopressin antagonists (conivaptan, lixivaptan, tolvaptan), which block the action of ADH and cause a water diuresis, are effective at correcting euvolemic hyponatremia, but overly rapid correction is a potential complication.

Treatment of chronic SIADH is challenging. Fluid restriction in children is difficult for nutritional and behavioral reasons. Other

options are long-term furosemide therapy with sodium supplementation, an oral vasopressin antagonist (tolvaptan), or oral urea.

55.4 Potassium

Larry A. Greenbaum

POTASSIUM METABOLISM

Body Content and Physiologic Function

The intracellular concentration of potassium, approximately 150 mEq/L, is much higher than the plasma concentration (see Fig. 55-3). The majority of body potassium is contained in muscle. As muscle mass increases, there is an increase in body potassium. There is thus an increase in body potassium during puberty, and it is more significant in males. The majority of extracellular potassium is in bone; <1% of total body potassium is in plasma.

Because most potassium is intracellular, the plasma concentration does not always reflect the total body potassium content. A variety of conditions alter the distribution of potassium between the intracellular and extracellular compartments. The Na^+,K^+-ATPase maintains the high intracellular potassium concentration by pumping sodium out of the cell and potassium into the cell. This activity balances the normal leak of potassium out of cells via potassium channels that is driven by the favorable chemical gradient. Insulin increases potassium movement into cells by activating the Na^+,K^+-ATPase. Hyperkalemia stimulates insulin secretion, which helps mitigate the hyperkalemia. Acid–base status affects potassium distribution, probably via potassium channels and the Na^+,K^+-ATPase. A decrease in pH drives potassium extracellularly; an increase in pH has the opposite effect. β-Adrenergic agonists stimulate the Na^+,K^+-ATPase, increasing cellular uptake of potassium. This increase is protective, in that hyperkalemia stimulates adrenal release of catecholamines. α-Adrenergic agonists and exercise cause a net movement of potassium out of the intracellular space. An increase in plasma osmolality, as with mannitol infusion, leads to water movement out of the cells, and potassium follows as a result of solvent drag. The serum potassium concentration increases by approximately 0.6 mEq/L with each 10-mOsm rise in plasma osmolality.

The high intracellular concentration of potassium, the principal intracellular cation, is maintained via the Na^+,K^+-ATPase. The resulting chemical gradient is used to produce the resting membrane potential of cells. Potassium is necessary for the electrical responsiveness of nerve and muscle cells and for the contractility of cardiac, skeletal, and smooth muscle. The changes in membrane polarization that occur during muscle contraction or nerve conduction make these cells susceptible to changes in serum potassium levels. The ratio of intracellular to extracellular potassium determines the threshold for a cell to generate an action potential and the rate of cellular repolarization. The intracellular potassium concentration affects cellular enzymes. Potassium is necessary for maintaining cell volume because of its important contribution to intracellular osmolality.

Intake

Potassium is plentiful in food. Dietary consumption varies considerably, even though 1-2 mEq/kg is the recommended intake. The intestines normally absorb approximately 90% of ingested potassium. Most absorption occurs in the small intestine, whereas the colon exchanges body potassium for luminal sodium. Regulation of intestinal losses normally has a minimal role in maintaining potassium homeostasis, although renal failure, aldosterone, and glucocorticoids increase colonic secretion of potassium. The increase in intestinal losses in the setting of renal failure and hyperkalemia, which stimulates aldosterone production, is clinically significant, helping to protect against hyperkalemia.

Excretion

There is some loss of potassium in sweat, but it is normally minimal. The colon has the ability to eliminate some potassium. In addition, after an acute potassium load, much of the potassium, >40%, moves intracellularly, through the actions of epinephrine and insulin, which are produced in response to hyperkalemia. This process provides transient protection from hyperkalemia, but most ingested potassium is eventually excreted in the urine. The kidneys principally regulate long-term potassium balance, and they alter excretion in response to a variety of signals. Potassium is freely filtered at the glomerulus, but 90% is resorbed before the distal tubule and collecting duct, the principal sites of potassium regulation. The distal tubule and the collecting duct have the ability to absorb and secrete potassium. It is the amount of tubular secretion that regulates the amount of potassium that appears in the urine. The plasma potassium concentration directly influences secretion in the distal nephron. As the potassium concentration increases, secretion increases.

The principal hormone regulating potassium secretion is aldosterone, which is released by the adrenal cortex in response to increased plasma potassium. Its main site of action is the cortical collecting duct, where aldosterone stimulates sodium movement from the tubule into the cells. This movement creates a negative charge in the tubular lumen, facilitating potassium excretion. In addition, the increased intracellular sodium stimulates the basolateral Na^+,K^+-ATPase, causing more potassium to move into the cells lining the cortical collecting duct. Glucocorticoids, ADH, a high urinary flow rate, and high sodium delivery to the distal nephron also increase urinary potassium excretion. Potassium excretion is decreased by insulin, catecholamines, and urinary ammonia. Whereas ADH increases potassium secretion, it also causes water resorption, decreasing urinary flow. The net effect is that ADH has little overall impact on potassium balance. Alkalosis causes potassium to move into cells, including the cells lining the collecting duct. This movement increases potassium secretion, and because acidosis has the opposite effect, it decreases potassium secretion.

The kidney can dramatically vary potassium excretion in response to changes in intake. Normally, approximately 10-15% of the filtered load is excreted. In an adult, excretion of potassium can vary from 5-1,000 mEq/day.

HYPERKALEMIA

Hyperkalemia—because of the potential for lethal arrhythmias—is one of the most alarming electrolyte abnormalities.

Etiology and Pathophysiology

Three basic mechanisms cause hyperkalemia (Table 55-4). In the individual patient, the etiology is sometimes multifactorial.

Spurious hyperkalemia or pseudohyperkalemia is very common in children because of the difficulties in obtaining blood specimens. This laboratory result is usually caused by hemolysis during a heelstick or phlebotomy, but it can be the result of prolonged tourniquet application or fist clenching, either of which causes local potassium release from muscle.

The serum potassium level is normally 0.4 mEq/L higher than the plasma value, secondary to potassium release from cells during clot formation. This phenomenon is exaggerated with thrombocytosis because of potassium release from platelets. For every 100,000/m^3 increase in the platelet count, the serum potassium level rises by approximately 0.15 mEq/L. This phenomenon also occurs with the marked white blood cell count elevations sometimes seen with leukemia. Elevated white blood cell counts, typically >200,000/m^3, can cause a dramatic elevation in the serum potassium concentration. Analysis of a plasma sample usually provides an accurate result. It is important to analyze the sample promptly to avoid potassium release from cells, which occurs if the sample is stored in the cold, or cellular uptake of potassium and spurious hypokalemia, which occurs with storage of the sample at room temperature. Occasionally, heparin causes lysis of leukemic cells and a false elevation of the plasma sample; a blood gas syringe has less heparin and may provide a more accurate reading than a standard tube. There are rare genetic disorders causing leakage of potassium from red cells that may causes familial pseudohyperkalemia.

Because of the kidney's ability to excrete potassium, it is unusual for excessive intake, by itself, to cause hyperkalemia. This condition can occur in a patient who is receiving large quantities of intravenous or oral potassium for excessive losses that are no longer present. Frequent or rapid blood transfusions can acutely increase the potassium level because of the potassium content of blood, which is variably elevated. Increased intake may precipitate hyperkalemia if there is an underlying defect in potassium excretion.

The intracellular space has a very high potassium concentration, so a shift of potassium from the intracellular space to the extracellular space can have a significant effect on the plasma potassium level. This shift occurs with metabolic acidosis, but the effect is minimal with an organic acid (lactic acidosis, ketoacidosis). A respiratory acidosis has less impact than a metabolic acidosis. Cell destruction, as seen with rhabdomyolysis, tumor lysis syndrome, tissue necrosis, or hemolysis, releases potassium into the extracellular milieu. The potassium released from red blood cells in internal bleeding, such as hematomas, is resorbed and enters the extracellular space.

Normal doses of succinylcholine or β-blockers and fluoride or digitalis intoxication all cause a shift of potassium out of the intracellular compartment. Succinylcholine should not be used during anesthesia in patients at risk for hyperkalemia. β-Blockers prevent the normal cellular uptake of potassium mediated by binding of β-agonists to the β_2-adrenergic receptors. Potassium release from muscle cells occurs during exercise, and levels can increase by 1-2 mEq/L with high activity. With an increased plasma osmolality, water moves from the intracellular space and potassium follows. This process occurs with hyperglycemia, although in nondiabetic patients, the resultant increase in insulin causes potassium to move intracellularly. In diabetic ketoacidosis, the absence of insulin causes potassium to leave the intracellular space, and the problem is compounded by the hyperosmolality. The effect of hyperosmolality causes a transcellular shift of potassium into the extracellular space after mannitol or hypertonic saline infusions. **Malignant hyperthermia,** which is triggered by some inhaled anesthetics, causes muscle release of potassium (see Chapter 611.2). **Hyperkalemic periodic paralysis** is an autosomal dominant disorder caused by a mutated sodium channel. It results in episodic cellular release of potassium and attacks of paralysis (see Chapter 611.1).

The kidneys excrete most of the daily potassium intake, so a decrease in kidney function can cause hyperkalemia. Newborn infants in general, and especially premature infants, have decreased kidney function at birth and thus are at increased risk for hyperkalemia despite an absence of intrinsic renal disease. Neonates also have decreased expression of potassium channels, further limiting potassium excretion.

A wide range of primary **adrenal disorders,** both hereditary and acquired, can cause decreased production of aldosterone, with secondary hyperkalemia (see Chapters 575 and 576). Patients with these disorders typically have metabolic acidosis and salt wasting with hyponatremia. Children with more subtle adrenal insufficiency may have electrolyte problems only during acute illnesses. The most common form of **congenital adrenal hyperplasia,** 21-hydroxylase deficiency, typically manifests in male infants as hyperkalemia, metabolic acidosis, hyponatremia, and volume depletion. Females with this disorder usually are diagnosed as newborns because of their ambiguous genitalia; treatment prevents the development of electrolyte problems.

Renin, via angiotensin II, stimulates aldosterone production. A deficiency in renin, a result of kidney damage, can lead to decreased aldosterone production. Hyporeninemia occurs in many kidney diseases, with some of the more common pediatric causes listed in Table 55-4. These patients typically have hyperkalemia and a metabolic acidosis, without hyponatremia. Some of these patients have impaired renal function, partially accounting for the hyperkalemia, but the impairment in potassium excretion is more extreme than expected for the degree of renal insufficiency.

A variety of **renal tubular disorders** impair renal excretion of potassium. Children with **pseudohypoaldosteronism type 1** have hyperkalemia, metabolic acidosis, and salt wasting leading to hyponatremia and volume depletion; aldosterone values are elevated. In the autosomal recessive variant, there is a defect in the renal sodium channel that is normally activated by aldosterone. Patients with this variant have severe symptoms, beginning in infancy. Patients with the autosomal dominant form have a defect in the aldosterone receptor, and the disease is milder, often remitting in adulthood. **Pseudohypoaldosteronism type 2 (familial hyperkalemic hypertension),** also called **Gordon syndrome,** is an autosomal dominant disorder characterized by hypertension caused by salt retention and impaired excretion of potassium and acid, leading to hyperkalemia and metabolic acidosis. Activating mutations in either WNK1 or WNK4, both serine-threonine kinases located in the distal nephron, cause Gordon syndrome. In the **Bartter syndrome** caused by

mutations in the potassium channel ROMK (type 2 Bartter syndrome), there can be transient hyperkalemia in neonates, but hypokalemia subsequently develops (see Chapter 531).

Acquired renal tubular dysfunction, with an impaired ability to excrete potassium, occurs in a number of conditions. These disorders, all characterized by tubulointerstitial disease, are often associated with impaired acid secretion and a secondary metabolic acidosis. In some affected children, the metabolic acidosis is the dominant feature, although a high potassium intake may unmask the defect in potassium handling. The tubular dysfunction can cause renal salt wasting, potentially leading to hyponatremia. Because of the tubulointerstitial damage, these conditions may also cause hyperkalemia as a result of hyporeninemic hypoaldosteronism.

The risk of hyperkalemia resulting from medications is greatest in patients with underlying renal insufficiency. The predominant mechanism of medication-induced hyperkalemia is impaired renal excretion, although angiotensin-converting enzyme inhibitors may worsen hyperkalemia in anuric patients, probably by inhibiting gastrointestinal potassium loss, which is normally upregulated in renal insufficiency. The hyperkalemia caused by trimethoprim generally occurs only at the very high doses used to treat *Pneumocystis jiroveci* pneumonia in patients with AIDS. Potassium-sparing diuretics may easily cause hyperkalemia, especially because they are often used in patients who are receiving oral potassium supplements. Oral contraceptives containing drospirenone, which blocks the action of aldosterone, may cause hyperkalemia and should not be used in patients with decreased renal function.

Clinical Manifestations

The most important effects of hyperkalemia are a result of the role of potassium in membrane polarization. The cardiac conduction system is usually the dominant concern. Changes in the electrocardiogram (ECG) begin with peaking of the T waves. This is followed, as the potassium level increases, by ST-segment depression, an increased PR interval, flattening of the P wave, and widening of the QRS complex. This process can eventually progress to ventricular fibrillation. Asystole may also occur. Some patients have paresthesias, fasciculations, weakness, and even an ascending paralysis, but cardiac toxicity usually precedes these clinical symptoms, emphasizing the danger of assuming that an absence of symptoms implies an absence of danger. Chronic hyperkalemia is generally better tolerated than acute hyperkalemia.

DIAGNOSIS

The etiology of hyperkalemia is often readily apparent. Spurious hyperkalemia is very common in children, so obtaining a second potassium measurement is often appropriate. If there is a significant elevation of the white blood cell or platelet count, the second measurement should be performed on a plasma sample that is evaluated promptly. The history should initially focus on potassium intake, risk factors for transcellular shifts of potassium, medications that cause hyperkalemia, and the presence of signs of renal insufficiency, such as oliguria and edema. Initial **laboratory evaluation** should include creatinine, BUN, and assessment of the acid–base status. Many etiologies of hyperkalemia cause a metabolic acidosis; a metabolic acidosis worsens hyperkalemia through the transcellular shift of potassium out of cells. Renal insufficiency is a common cause of the combination of metabolic acidosis and hyperkalemia. This association is also seen in diseases associated with aldosterone insufficiency or aldosterone resistance. Children with absence of or ineffective aldosterone often have hyponatremia and volume depletion because of salt wasting. Genetic diseases, such as congenital adrenal hyperplasia and pseudohypoaldosteronism, usually manifest in infancy and should be strongly considered in the infant with hyperkalemia and metabolic acidosis, especially if hyponatremia is present. It is important to consider the various etiologies of a transcellular shift of potassium. In some of these disorders, the potassium level continues to increase, despite the elimination of all potassium intake, especially when there is concurrent renal insufficiency. This increase is potentially seen in tumor lysis syndrome, hemolysis, rhabdomyolysis, and other causes of cell death. All of these entities can cause concomitant hyperphosphatemia and hyperuricemia. Rhabdomyolysis produces an elevated creatinine phosphokinase (CPK) value and hypocalcemia, whereas children with hemolysis have hemoglobinuria and a decreasing hematocrit. For the child with diabetes, an elevated blood glucose value suggests a transcellular shift of potassium.

Treatment

The plasma potassium level, the ECG, and the risk of the problem worsening determine the aggressiveness of the therapeutic approach. High serum potassium levels and the presence of ECG changes require vigorous treatment. An additional source of concern is the patient in whom plasma potassium levels are rising despite minimal intake. This situation can happen if there is cellular release of potassium (tumor lysis syndrome), especially in the setting of diminished excretion (renal failure).

The first action in a child with a concerning elevation of plasma potassium is to stop all sources of additional potassium (oral, intravenous). Washed red blood cells can be used for patients who require blood transfusions. If the potassium level is >6.5 mEq/L, an ECG should be obtained to help assess the urgency of the situation. Peak T waves are the first sign of hyperkalemia followed by a prolonged PR interval and, when most severe, a prolonged QRS complex. Life-threatening ventricular arrhythmias may also develop. The treatment of hyperkalemia has 2 basic goals: (a) to stabilize the heart to prevent life-threatening arrhythmias and (b) to remove potassium from the body. The treatments that acutely prevent arrhythmias all have the advantage of working quickly (within minutes) but do not remove potassium from the body. *Calcium stabilizes the cell membrane of heart cells, preventing arrhythmias.* It is given intravenously over a few minutes, and its action is almost immediate. Calcium should be given over 30 min in a patient who is receiving digitalis, because otherwise the calcium may cause arrhythmias. Bicarbonate causes potassium to move intracellularly, lowering the plasma potassium level. It is most efficacious in a patient with a metabolic acidosis. Insulin causes potassium to move intracellularly but must be given with glucose to avoid hypoglycemia. The combination of insulin and glucose works within 30 min. Nebulized albuterol, by stimulation of β_1-receptors, leads to rapid intracellular movement of potassium. This has the advantage of not requiring an intravenous route of administration, allowing it to be given concurrently with the other measures.

It is critical to begin measures that remove potassium from the body. In patients who are not anuric, a loop diuretic increases renal excretion of potassium. A high dose may be required in a patient with significant renal insufficiency. Sodium polystyrene sulfonate (Kayexalate) is an exchange resin that is given either rectally or orally. Sodium in the resin is exchanged for body potassium, and the potassium-containing resin is then excreted from the body. Some patients require dialysis for acute potassium removal. Dialysis is often necessary if the patient has either severe renal failure or an especially high rate of endogenous potassium release, as is sometimes present with tumor lysis syndrome or rhabdomyolysis. Hemodialysis rapidly lowers plasma potassium levels. Peritoneal dialysis is not nearly as quick or reliable, but it is usually adequate as long as the acute problem can be managed with medications and the endogenous release of potassium is not high.

Long-term management of hyperkalemia includes reducing intake via dietary changes and eliminating or reducing medications that cause hyperkalemia (see Chapter 535). Some patients require medications to increase potassium excretion, such as sodium polystyrene sulfonate and loop or thiazide diuretics. Some infants with chronic renal failure may need to start dialysis to allow adequate caloric intake without hyperkalemia. It is unusual for an older child to require dialysis principally to control chronic hyperkalemia. The disorders that are caused by a deficiency in aldosterone respond to replacement therapy with fludrocortisone.

HYPOKALEMIA

Hypokalemia is common in children, with most cases related to gastroenteritis.

Etiology and Pathophysiology

There are 4 basic mechanisms of hypokalemia (Table 55-5). Spurious hypokalemia occurs in patients with leukemia and very elevated white blood cell counts if plasma for analysis is left at room temperature, permitting the white blood cells to take up potassium from the plasma. With a transcellular shift, there is no change in total body potassium, although there may be concomitant potassium depletion resulting from other factors. Decreased intake, extrarenal losses, and renal losses are all associated with total body potassium depletion.

Because the intracellular potassium concentration is much higher than the plasma level, a significant amount of potassium can move into cells without markedly changing the intracellular potassium concentration. Alkalemia is one of the more common causes of a transcellular shift. The effect is much greater with a metabolic alkalosis than with a respiratory alkalosis. The impact of exogenous insulin on potassium movement into the cells is substantial in patients with diabetic ketoacidosis. Endogenous insulin may be the cause when a patient is given a bolus of glucose. Both endogenous (epinephrine in stress) and exogenous (albuterol) β-adrenergic agonists stimulate cellular uptake of potassium. Theophylline overdose, barium intoxication, administration of cesium chloride (a homeopathic cancer remedy), and toluene intoxication from paint or glue sniffing can cause a transcellular shift hypokalemia, often with severe clinical manifestations. Children with **hypokalemic periodic paralysis,** a rare autosomal dominant disorder, have acute cellular uptake of potassium (see Chapter 611). **Thyrotoxic periodic paralysis,** which is more common in Asians, is an unusual initial manifestation of hyperthyroidism. Affected patients have dramatic hypokalemia as a result of a transcellular shift of potassium. Hypokalemia can occur during refeeding syndrome (see Chapter 338.8).

Inadequate potassium intake occurs in **anorexia nervosa;** accompanying bulimia and laxative or diuretic abuse exacerbates the potassium deficiency. Sweat losses of potassium can be significant during vigorous exercise in a hot climate. Associated volume depletion and hyperaldosteronism increase renal losses of potassium (discussed later). Diarrheal fluid has a high concentration of potassium, and hypokalemia as a result of diarrhea is usually associated with a metabolic acidosis resulting from stool losses of bicarbonate. In contrast, a normal acid–base balance or a mild metabolic alkalosis is seen with laxative abuse. Intake of sodium polystyrene sulfonate or ingestion of clay because of pica increases stool losses of potassium.

Urinary potassium wasting may be accompanied by a metabolic acidosis (proximal or distal RTA). In diabetic ketoacidosis, although it is often associated with normal plasma potassium caused by transcellular shifts, there is significant total body potassium depletion from urinary losses because of the osmotic diuresis, and the potassium level may decrease dramatically with insulin therapy (see Chapter 589). Both the polyuric phase of acute tubular necrosis and postobstructive diuresis cause transient, highly variable potassium wasting and may be associated with a metabolic acidosis. Tubular damage, which occurs either directly from medications or secondary to interstitial nephritis, is often accompanied by other tubular losses of nutrients, including magnesium, sodium, and water. Such tubular damage may cause a secondary RTA with a metabolic acidosis. Isolated magnesium deficiency causes renal potassium wasting. Penicillin is an anion that is excreted in the urine, resulting in increased potassium excretion because the penicillin anion must be accompanied by a cation. Hypokalemia from penicillin therapy occurs only with the sodium salt of penicillin, not with the potassium salt.

Urinary potassium wasting is often accompanied by a metabolic alkalosis. This condition is usually associated with increased aldosterone, which increases urinary potassium and acid losses, contributing to the hypokalemia and the metabolic alkalosis. Other mechanisms often contribute to both the potassium losses and the metabolic alkalosis. With emesis or nasogastric suction, there is gastric loss of potassium, but this is fairly minimal, given the low potassium content of gastric fluid (≈10 mEq/L). More important is the gastric loss of hydrochloric acid (HCl), leading to a metabolic alkalosis and a state of volume depletion. The kidney compensates for the metabolic alkalosis by excreting bicarbonate in the urine, but there is obligate loss of potassium and sodium with the bicarbonate. The volume depletion raises aldosterone levels, further increasing urinary potassium losses and preventing correction of the metabolic alkalosis and hypokalemia until the volume depletion is corrected. Urinary chloride is low as a response to the volume depletion. Because the volume depletion is secondary to chloride loss, this is a state of chloride deficiency. There

*Most cases of proximal renal tubular acidosis are not caused by this primary genetic disorder. Proximal renal tubular acidosis is usually part of Fanconi syndrome, which has multiple etiologies.

EAST, epilepsy, ataxia, sensorineural hearing loss, and tubulopathy; OMIM, database number from the Online Mendelian Inheritance in Man (http://www.ncbi.nlm.nih.gov/omim).

were cases of chloride deficiency resulting from infant formula deficient in chloride, which caused a metabolic alkalosis with hypokalemia and low urine chloride levels. Current infant formula is not deficient in chloride. A similar mechanism occurs in cystic fibrosis because of chloride loss in sweat. In **congenital chloride-losing diarrhea**, an autosomal recessive disorder, there is high stool loss of chloride, leading to metabolic alkalosis, an unusual sequela of diarrhea. Because of stool potassium losses, chloride deficiency, and metabolic alkalosis, patients with this disorder have hypokalemia. During respiratory acidosis, there is renal compensation, with retention of bicarbonate and excretion of chloride. After the respiratory acidosis is corrected, the patients have chloride deficiency and posthypercapnic alkalosis with secondary hypokalemia. Patients with chloride deficiency, metabolic alkalosis, and hypokalemia have a urinary chloride level of <10 mEq/L. Loop and thiazide diuretics lead to hypokalemia, metabolic alkalosis, and chloride deficiency. During treatment, these patients have high urine chloride levels resulting from the effect of the diuretic. However, after the diuretics are discontinued, there is residual chloride deficiency, the urinary chloride level is appropriately low, and neither the hypokalemia nor the alkalosis resolves until the chloride deficiency is corrected.

The combination of metabolic alkalosis, hypokalemia, a high urine chloride level, and normal blood pressure is characteristic of **Bartter syndrome, Gitelman syndrome,** and **current diuretic use.** Patients with any of these conditions have high urinary losses of potassium and chloride, despite a state of relative volume depletion with secondary hyperaldosteronism. Bartter and Gitelman syndromes are autosomal recessive disorders caused by defects in tubular transporters (see Chapter 531). Bartter syndrome is usually associated with hypercalciuria, and often with nephrocalcinosis, whereas children with Gitelman syndrome have low urinary calcium losses but hypomagnesemia as a consequence of urinary magnesium losses. Some patients with Bartter syndrome have hypomagnesemia.

Some patients with hypoparathyroidism and hypocalcemia caused by an activating mutation of the calcium-sensing receptor (autosomal dominant hypoparathyroidism) have hypokalemia, hypomagnesemia, and metabolic alkalosis. The reason is that activation of the calcium-sensing receptor in the loop of Henle impairs tubular resorption of sodium and chloride, causing volume depletion and secondary hyperaldosteronism. **EAST syndrome,** an autosomal recessive disorder caused by mutations in the gene for a potassium channel present in the kidney, inner ear, and brain, consists of epilepsy, ataxia, sensorineural hearing loss, and tubulopathy (hypokalemia, metabolic alkalosis, hypomagnesemia, and hypocalciuria).

In the presence of high aldosterone levels, there is urinary loss of potassium, hypokalemia, metabolic alkalosis, and an elevated urinary chloride level. Also, renal retention of sodium leads to hypertension. Primary hyperaldosteronism caused by adenoma or hyperplasia is much less common in children than in adults (see Chapter 578). Glucocorticoid-remediable aldosteronism, an autosomal dominant disorder that leads to high levels of aldosterone, is often diagnosed in childhood, although hypokalemia is not always present.

Increased aldosterone levels may be secondary to increased renin production. Renal artery stenosis leads to hypertension from increased renin and secondary hyperaldosteronism. The increased aldosterone can cause hypokalemia and metabolic alkalosis, although most patients have normal electrolyte levels. Renin-producing tumors, which are extremely rare, can cause hypokalemia.

A variety of disorders cause hypertension and hypokalemia without increased aldosterone levels. Some are a result of increased levels of mineralocorticoids other than aldosterone. Such increases occur in 2 forms of **congenital adrenal hyperplasia** (see Chapter 576). In 11β-hydroxylase deficiency, which is associated with virilization, the value of 11-deoxycorticosterone is elevated, causing variable hypertension and hypokalemia. A similar mechanism, increased 11-deoxycorticosterone, occurs in 17α-hydroxylase deficiency, but patients with this disorder are more uniformly hypertensive and hypokalemic, and they have a defect in sex hormone production. Cushing syndrome, frequently associated with hypertension, less commonly causes metabolic alkalosis and hypokalemia. This is secondary to the mineralocorticoid activity of cortisol. In 11β-hydroxysteroid dehydrogenase deficiency, an autosomal recessive disorder, the enzymatic defect prevents the conversion of cortisol to cortisone in the kidney. Because cortisol binds to and activates the aldosterone receptor, children with this deficiency have all the features of excessive mineralocorticoids, including hypertension, hypokalemia, and metabolic alkalosis. Patients with this disorder, which is also called apparent mineralocorticoid excess, respond to spironolactone therapy, which blocks the mineralocorticoid receptor. An acquired form of 11β-hydroxysteroid dehydrogenase deficiency occurs from the ingestion of substances that inhibit this enzyme. A classic example is glycyrrhizic acid, which is found in natural licorice. **Liddle syndrome** is an autosomal dominant disorder that results from an activating mutation of the distal nephron sodium channel that is normally upregulated by aldosterone. Patients have the characteristics of hyperaldosteronism—hypertension, hypokalemia, and alkalosis—but low serum aldosterone levels. These patients respond to the potassium-sparing diuretics (triamterene and amiloride) that inhibit this sodium channel (see Chapter 531.3).

Clinical Manifestations

The heart and skeletal muscle are especially vulnerable to hypokalemia. ECG changes include a flattened T wave, a depressed ST segment, and the appearance of a U wave, which is located between the T wave (if still visible) and the P wave. Ventricular fibrillation and torsades de pointes may occur, although usually only in the context of underlying heart disease. Hypokalemia makes the heart especially susceptible to digitalis-induced arrhythmias, such as supraventricular tachycardia, ventricular tachycardia, and heart block (see Chapter 435).

The clinical consequences of hypokalemia in skeletal muscle include muscle weakness and cramps. Paralysis is a possible complication, generally only at potassium levels <2.5 mEq/L. It usually starts in the legs and moves to the arms. Respiratory paralysis may require mechanical ventilation. Some patients have rhabdomyolysis; the risk increases with exercise. Hypokalemia slows gastrointestinal motility. This effect manifests as constipation; with potassium levels <2.5 mEq/L, an ileus may occur. Hypokalemia impairs bladder function, potentially leading to urinary retention.

Hypokalemia causes **polyuria** and **polydipsia** by impairing urinary concentrating ability, which produces nephrogenic diabetes insipidus. Hypokalemia stimulates renal ammonia production, an effect that is clinically significant if hepatic failure is present, because the liver cannot metabolize the ammonia. Consequently, hypokalemia may worsen hepatic encephalopathy. Chronic hypokalemia may cause kidney damage, including interstitial nephritis and renal cysts.

Diagnosis

Most causes of hypokalemia are readily apparent from the history. It is important to review the child's diet, gastrointestinal losses, and medications. Both emesis and diuretic use can be surreptitious. The presence of hypertension suggests excess mineralocorticoids. Concomitant electrolyte abnormalities are useful clues. The combination of hypokalemia and metabolic acidosis is characteristic of diarrhea and of distal and proximal RTA. A concurrent metabolic alkalosis is characteristic of emesis or nasogastric losses, aldosterone excess, use of diuretics, and Bartter and Gitelman syndromes. Figure 55-5 shows an approach to persistent hypokalemia.

If a clear etiology is not apparent, the measurement of urinary potassium distinguishes between renal and extrarenal losses. The kidneys should conserve potassium in the presence of extrarenal losses. Urinary potassium losses can be assessed with a 24 hr urine collection, a spot potassium : creatinine ratio, a fractional excretion of potassium, or calculation of the transtubular potassium gradient (TTKG), which is the most widely used approach in children:

$$\text{TTKG} = [K]_{urine}/[K]_{plasma} \times (\text{plasma osmolality/urine osmolality})$$

where $[K]_{urine}$ = urine potassium concentration and $[K]_{plasma}$ = plasma potassium concentration.

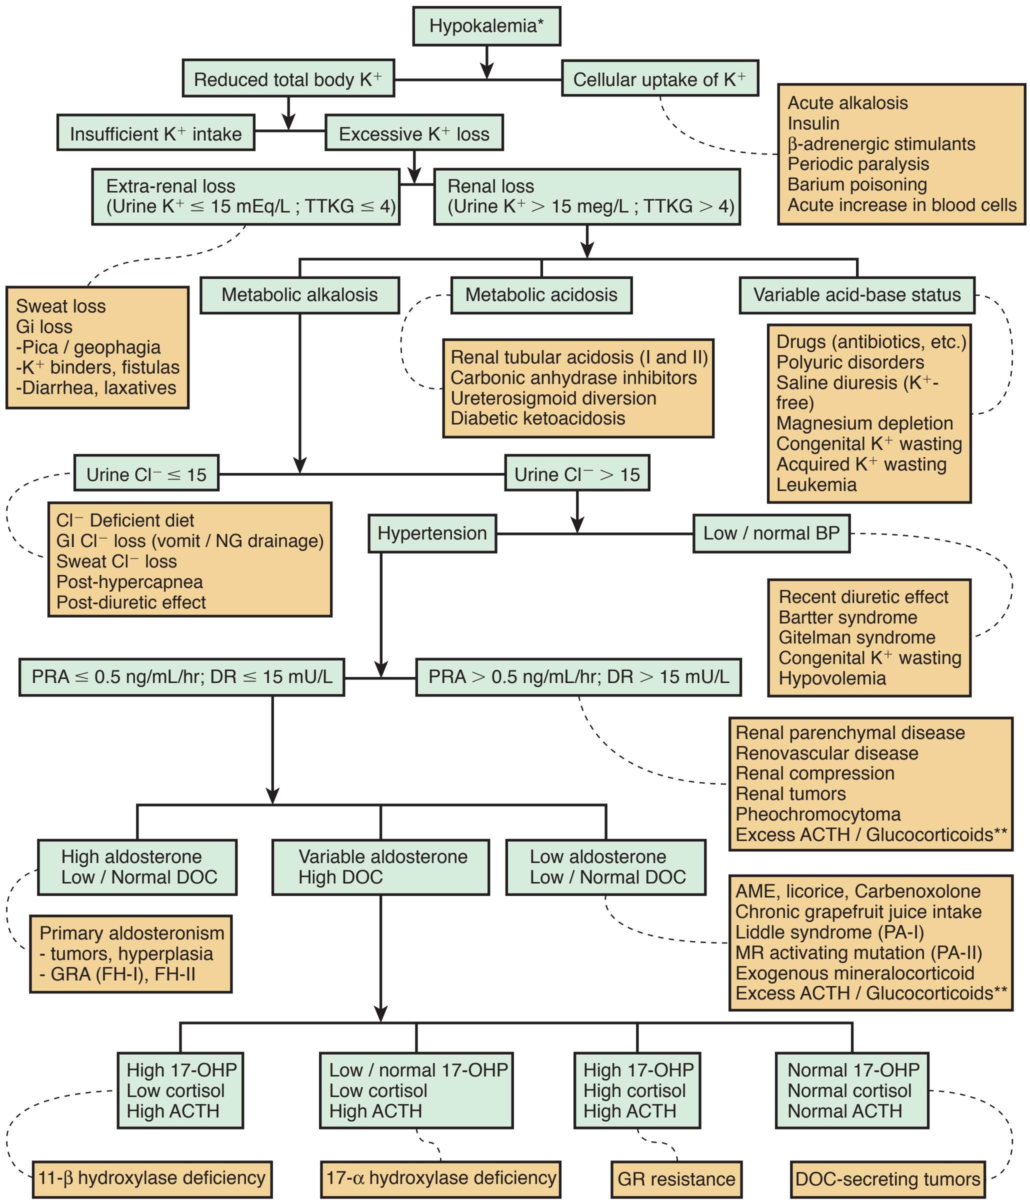

Figure 55-5 Diagnostic algorithm to evaluate persistent hypokalemia. *Spurious hypokalemia must be excluded. **Hypokalemia is uncommon in uncomplicated edematous disorders and in conditions associated with excessive glucocorticosteroids. Conditions associated with high circulating levels of glucocorticosteroids often have normal renin activity. 17-OHP, 17-hydroxyprogesterone; ACTH, adrenocorticotropic hormone; AME, apparent mineralocorticoid excess; BP, blood pressure; Cl^-, chloride; DOC, 11-deoxycorticosterone; DR, direct renin assay; GI, gastrointestinal; FH-II, familial hyperaldosteronism type II; GR, glucocorticoid receptor; GRA (FH-I), glucocorticoid remediable aldosteronism (familial hyperaldosteronism type I); K^+, potassium; MR, mineralocorticoid receptor; PA-I, pseudoaldosteronism type I; PA-II, pseudoaldosteronism type II; PRA, plasma renin activity; TTKG, transtubular potassium gradient. *(From Shoemaker LR, Eaton BV, Buchino JJ: A three-year-old with persistent hypokalemia, J Pediatr 151:696–699, 2007.)*

The urine osmolality must be greater than the serum osmolality for the result of this calculation to be valid. A TTKG >4 in the presence of hypokalemia suggests excessive urinary losses of potassium. The urinary potassium excretion value can be misleading if the stimulus for renal loss, such as a diuretic, is no longer present.

Treatment

Factors that influence the treatment of hypokalemia include the potassium level, clinical symptoms, renal function, the presence of transcellular shifts of potassium, ongoing losses, and the patient's ability to tolerate oral potassium. Severe, symptomatic hypokalemia requires aggressive treatment. Supplementation is more cautious if renal function is decreased because of the kidney's limited ability to excrete excessive potassium. The plasma potassium level does not always provide an accurate estimation of the total body potassium deficit because there may be shifts of potassium from the intracellular space to the plasma. Clinically, such shifts occur most commonly with metabolic acidosis and the insulin deficiency of diabetic ketoacidosis; the plasma potassium measurement underestimates the degree of total body potassium depletion. When these problems are corrected, potassium moves into the intracellular space, so more potassium supplementation is required to correct the hypokalemia. Likewise, the presence of a transcellular shift of potassium into the cells indicates that the total body potassium depletion is less severe. In an isolated transcellular shift, as occurs in hypokalemic periodic paralysis, potassium supplementation should be used cautiously,

given the risk of hyperkalemia when the transcellular shift resolves. This caution is especially required in thyrotoxic periodic paralysis, which responds dramatically to propranolol, with correction of weakness and hypokalemia. Patients who have ongoing losses of potassium need correction of the deficit and replacement of the ongoing losses.

Because of the risk of hyperkalemia, intravenous potassium should be used very cautiously. Oral potassium is safer, albeit not as rapid in urgent situations. Liquid preparations are bitter tasting; microencapsulated or wax matrix formulations are less irritating than tablets to the gastric mucosa (oral dose: 2-4 mEq/kg/day with a maximum of 120-240 mEq/day in divided doses). The dose of intravenous potassium is 0.5-1.0 mEq/kg, usually given over 1 hr. The adult maximum dose is 40 mEq. Conservative dosing is generally preferred. Potassium chloride is the usual choice for supplementation, although the presence of concurrent electrolyte abnormalities may dictate other options. Patients with acidosis and hypokalemia can receive potassium acetate or potassium citrate. If hypophosphatemia is present, then some of the potassium deficit can be replaced with potassium phosphate. It is sometimes possible to decrease ongoing losses of potassium. For patients with excessive urinary losses, potassium-sparing diuretics are effective, but they need to be used cautiously in patients with renal insufficiency. If hypokalemia, metabolic alkalosis, and volume depletion are present (with gastric losses), then restoration of intravascular volume with adequate sodium chloride will decrease urinary potassium losses. Correction of concurrent hypomagnesemia is important because hypomagnesemia may cause hypokalemia. Disease-specific therapy is effective in many of the genetic tubular disorders.

55.5 Magnesium

Larry A. Greenbaum

MAGNESIUM METABOLISM

Body Content and Physiologic Function

Magnesium is the fourth most common cation in the body and the third most common intracellular cation (see Fig. 55-3). Between 50% and 60% of body magnesium is in bone, where it serves as a reservoir because 30% is exchangeable, allowing movement to the extracellular space. Most intracellular magnesium is bound to proteins; only approximately 25% is exchangeable. Because cells with higher metabolic rates have higher magnesium concentrations, most intracellular magnesium is present in muscle and liver.

The normal plasma magnesium concentration is 1.5-2.3 mg/dL (1.2-1.9 mEq/L; 0.62-0.94 mmol/L), with some variation among clinical laboratories. Infants have slightly higher plasma magnesium concentrations than older children and adults. Only 1% of body magnesium is extracellular (60% ionized; 15% complexed; 25% protein bound). In the United States, serum magnesium is reported as mg/dL (Table 55-6).

Table 55-6 Conversion Factors for Calcium, Magnesium, and Phosphorus

	UNIT	CONVERSION FACTOR	UNIT
Calcium	mg/dL	0.25	mmol/L
	mEq/L	0.5	mmol/L
	mg/dL	0.5	mEq/L
Magnesium	mg/dL	0.411	mmol/L
	mEq/L	0.5	mmol/L
	mg/dL	0.822	mEq/L
Phosphorus	mg/dL	0.32	mmol/L

Values in the left-column unit are converted into the right-column unit via multiplying by the conversion factor (e.g., calcium of 10 mg/dL × 0.25 = 2.5 mmol/L). Division of the right-column unit by the conversion factor converts to the units of the left-column unit.

Magnesium is a necessary cofactor for hundreds of enzymes. It is important for membrane stabilization and nerve conduction. Adenosine triphosphate (ATP) and guanosine triphosphate need associated magnesium when they are used by adenosine triphosphatases, cyclases, and kinases.

Intake

Between 30% and 50% of dietary magnesium is absorbed. Good dietary sources include green vegetables, cereals, nuts, meats, and hard water, although many foods contain magnesium. Human milk contains approximately 35 mg/L of magnesium; formula contains 40-70 mg/L. The small intestine is the major site of magnesium absorption, but the regulation of magnesium absorption is poorly understood. There is passive absorption, which permits high absorption in the presence of excessive intake. It probably occurs via a paracellular mechanism. Absorption is diminished in the presence of substances that complex with magnesium (free fatty acids, fiber, phytate, phosphate, oxalate); increased intestinal motility and calcium also decrease magnesium absorption. Vitamin D and parathyroid hormone (PTH) may enhance absorption, although this effect is limited. Intestinal absorption does increase when intake is decreased, possibly via a saturable active transport system. If there is no oral intake of magnesium, obligatory secretory losses prevent the complete elimination of intestinal losses.

Excretion

Renal excretion is the principal regulator of magnesium balance. There is no defined hormonal regulatory system, although PTH may increase tubular resorption. Approximately 15% of resorption occurs in the proximal tubule, and 70% in the thick ascending limb (TAL) of the loop of Henle. Proximal resorption may be higher in neonates. High serum magnesium levels inhibit resorption in the TAL, suggesting that active transport is involved. Approximately 5-10% of filtered magnesium is resorbed in the distal tubule. Hypomagnesemia increases absorption in the TAL and the distal tubule.

HYPOMAGNESEMIA

Hypomagnesemia is relatively common in hospitalized patients, although most cases are asymptomatic. Detection requires a high index of suspicion because magnesium is not measured in most basic metabolic panels.

Etiology and Pathophysiology

Gastrointestinal and renal losses are the major causes of hypomagnesemia (Table 55-7). Diarrheal fluid contains up to 200 mg/L of magnesium; gastric contents have only approximately 15 mg/L, but high losses can cause depletion. Steatorrhea causes magnesium loss as a result of the formation of magnesium-lipid salts; restriction of dietary fat can decrease losses.

Hypomagnesemia with secondary hypocalcemia, a rare autosomal recessive disorder, is caused by decreased intestinal absorption of magnesium and renal magnesium wasting. Patients with this disorder have mutations in a gene (*TRPM6*) that is expressed in intestine and kidney. TRPM6 codes for a transient receptor potential cation channel. The patients have seizures, tetany, tremor, or restlessness at 2-8 wk of life as a result of severe hypomagnesemia (0.2-0.8 mg/dL) and secondary hypocalcemia.

Renal losses may occur because of medications that are direct tubular toxins. Amphotericin frequently causes significant magnesium wasting and is typically associated with other tubular defects (especially potassium wasting). Cisplatin produces dramatic renal magnesium losses. Diuretics affect tubular handling of magnesium. Loop diuretics cause a mild increase in magnesium excretion, and thiazide diuretics have even less effect. Chronic use of proton pump inhibitors may cause hypomagnesemia. Potassium-sparing diuretics reduce magnesium losses. Osmotic agents, such as mannitol, glucose in diabetes

mellitus, and urea in the recovery phase of acute tubular necrosis, increase urinary magnesium losses. Epidermal growth factor receptor inhibitors cause renal magnesium wasting. Intravenous fluid, by expanding the intravascular volume, decreases renal resorption of sodium and water, thereby impairing magnesium resorption. Hypercalcemia inhibits magnesium resorption in the loop of Henle, although this inhibition does not occur in hypercalcemia caused by familial hypercalcemic hypocalciuria or lithium.

A number of rare genetic diseases cause renal magnesium loss. **Gitelman and Bartter syndromes,** both autosomal recessive disorders, are the most common entities (see Chapter 531). Gitelman syndrome, which is caused by a defect in the thiazide-sensitive Na^+-Cl^- cotransporter in the distal tubule, is usually associated with hypomagnesemia. Hypomagnesemia occurs in a minority of patients with Bartter syndrome, which can be caused by mutations in multiple genes that are necessary for sodium and chloride reabsorption in the loop of Henle. In both disorders, there is hypokalemic metabolic alkalosis. Typically, hypomagnesemia is not severe and is asymptomatic, although tetany as a result of hypomagnesemia occasionally occurs.

Familial hypomagnesemia with hypercalciuria and nephrocalcinosis (Michelis-Castrillo syndrome), an autosomal recessive disorder, is caused by mutations in the gene for claudin 16 (paracellin-1), which is located in the tight junctions of the TAL of the loop of Henle. Patients with the disease have severe renal wasting of magnesium and calcium with secondary hypomagnesemia and nephrocalcinosis; serum calcium levels are normal. Chronic renal failure frequently occurs during childhood. Other features include kidney stones, urinary tract infections, hematuria, increased PTH levels, tetany, seizures, incomplete distal RTA, hyperuricemia, polyuria, and polydipsia. Patients with **familial hypomagnesemia with hypercalciuria, nephrocalcinosis, and severe ocular involvement** have mutations in the gene for claudin 19.

Autosomal recessive renal magnesium wasting with normocalciuria is caused by mutations in the epidermal growth factor gene. Clinical manifestations include seizures, mild to moderate psychomotor retardation, and brisk tendon reflexes.

Autosomal dominant renal magnesium wasting is caused by mutations in a number of different genes. A dominant-negative mutation in the gene encoding the Na^+,K^+-adenosine triphosphatase γ subunit is associated with hypomagnesemia, increased urinary magnesium losses, hypocalciuria, and normocalcemia. Patients may present with seizures; most are asymptomatic, despite serum magnesium levels of 0.8-1.5 mg/dL. Mutations in *CNNM2*, which encodes a protein that mediates magnesium-sensitive sodium currents, cause isolated hypomagnesemia. A mutation in *KCNA1*, a gene that encodes a potassium channel, also causes an autosomal dominant form of hypomagnesemia; symptoms may be severe.

Renal cysts and diabetes syndrome, which is caused by mutations in the gene for hepatocyte nuclear factor-1β, is associated with hypomagnesemia, despite the frequent presence of renal insufficiency. The hypomagnesemia is usually mild but may cause symptomatic hypocalcemia. **EAST syndrome** is caused by mutations in a potassium channel, and patients with this autosomal recessive disorder have hypokalemia, metabolic alkalosis, and hypomagnesemia. **Autosomal dominant hypoparathyroidism** is caused by an activating mutation in the calcium-sensing receptor, which also senses magnesium levels in the kidney (see Chapter 571). The mutated receptor inappropriately perceives that magnesium and calcium levels are elevated, leading to urinary wasting of both cations. Hypomagnesemia, if present, is usually mild. A mutation in a mitochondrially encoded transfer RNA is associated with hypomagnesemia, hypertension, and hypercholesterolemia. Hypomagnesemia is occasionally present in children with other mitochondrial disorders.

Poor intake is an unusual cause of hypomagnesemia, although it can be seen in children who are hospitalized and receive only intravenous fluids without magnesium. In **hungry bone syndrome,** which most frequently occurs after parathyroidectomy in patients with hyperparathyroidism, magnesium moves into bone as a result of accelerated bone formation. These patients usually have hypocalcemia and hypophosphatemia via the same mechanism. A similar mechanism can occur during the **refeeding phase of protein-calorie malnutrition** in children, with high magnesium use during cell growth depleting the patient's limited reserves. Insulin therapy stimulates uptake of magnesium by cells, and in diabetic ketoacidosis, in which total body magnesium is low because of osmotic losses, hypomagnesemia frequently occurs. In **pancreatitis,** there is saponification of magnesium and calcium in necrotic fat, causing both hypomagnesemia and hypocalcemia.

Transient hypomagnesemia in newborns, which is sometimes idiopathic, is more commonly seen in infants of diabetic mothers, presumably as a result of maternal depletion from osmotic losses. Other maternal diseases that cause magnesium losses predispose infants to hypomagnesemia. Hypomagnesemia is more common in infants with intrauterine growth restriction. Hypomagnesemia may develop in newborn infants who require exchange transfusions because of magnesium removal by the citrate in banked blood.

Clinical Manifestations

Hypomagnesemia causes secondary hypocalcemia by impairing the release of PTH by the parathyroid gland and through blunting of the tissue response to PTH. Thus, hypomagnesemia is part of the differential diagnosis of hypocalcemia (see Chapter 571). It usually occurs only at magnesium levels <0.7 mg/dL. The dominant manifestations of hypomagnesemia are caused by hypocalcemia: tetany, presence of Chvostek and Trousseau signs, and seizures. However, with severe hypomagnesemia, these same signs and symptoms may be present despite normocalcemia. Persistent hypocalcemia caused by hypomagnesemia is a rare cause of rickets.

Many causes of hypomagnesemia also result in hypokalemia. Hypomagnesemia may produce renal potassium wasting and hypokalemia that corrects only with magnesium therapy. ECG changes with hypomagnesemia include flattening of the T wave and lengthening of the ST segment. Arrhythmias may occur, almost always in the setting of underlying heart disease.

Diagnosis

The etiology of hypomagnesemia is often readily apparent from the clinical situation. The child should be assessed for gastrointestinal disease, adequate intake, and kidney disease, with close attention paid to medications that may cause renal magnesium wasting. When the diagnosis is uncertain, an evaluation of urinary magnesium losses distinguishes between renal and nonrenal causes. The fractional excretion of magnesium (FE_{Mg}) is calculated via the following formula:

$$FE_{Mg} = (U_{Mg} \times P_{Cr})/([0.7 \times P_{Mg}] \times U_{Cr}) \times 100$$

where U_{Mg} is urinary magnesium concentration, P_{Cr} is plasma creatinine concentration, P_{Mg} is plasma magnesium concentration, and U_{Cr} is urinary magnesium concentration. The plasma magnesium concentration is multiplied by 0.7 because approximately 30% is bound to albumin and not filtered at the glomerulus.

The FE_{Mg} does not vary with age, but it does change according to the serum magnesium concentration. The FE_{Mg} ranges from 1-8% in children with normal magnesium levels. In the presence of hypomagnesemia as a result of extrarenal causes, it should be low because of renal conservation, typically <2%. The FE_{Mg} is inappropriately elevated in the setting of renal magnesium wasting; values are usually >4% and frequently are >10%. The measurement should not be made during a magnesium infusion, because the acute increase in serum magnesium increases urinary magnesium. Other approaches for evaluating urinary magnesium losses include calculation of 24 hr urinary magnesium losses and of the ratio of urine magnesium : urine creatinine, both of which vary with age.

The genetic causes of renal magnesium loss are distinguished on the basis of the measurement of other serum and urinary electrolytes. Children with Gitelman and Bartter syndromes have hypokalemia and metabolic alkalosis.

Treatment

Severe hypomagnesemia is treated with parenteral magnesium. Magnesium sulfate is given at a dose of 25-50 mg/kg (0.05-0.1 mL/kg of a 50% solution; 2.5-5.0 mg/kg of elemental magnesium). It is administered as a slow intravenous infusion, although it may be given intramuscularly in neonates. The rate of intravenous infusion should be slowed if a patient experiences diaphoresis, flushing, or a warm sensation. The dose is often repeated every 6 hr (every 8-12 hr in neonates), for a total of 2-3 doses, before the plasma magnesium concentration is rechecked. Lower doses are used in children with renal insufficiency.

Long-term therapy is usually given orally. Preparations include magnesium gluconate (5.4 mg elemental magnesium/100 mg), magnesium oxide (60 mg elemental magnesium/100 mg), and magnesium sulfate (10 mg elemental magnesium/100 mg). There are sustained-released preparations, such as Slow-Mag (60 mg elemental magnesium/tablet) and Mag-Tab SR (84 mg elemental magnesium/tablet). Oral magnesium dosing should be divided to decrease cathartic side effects. Alternatives to oral magnesium are intramuscular injections and nighttime nasogastric infusion, both designed to minimize diarrhea. Magnesium supplementation must be used cautiously in the context of renal insufficiency.

HYPERMAGNESEMIA

Clinically significant hypermagnesemia is almost always secondary to excessive intake. It is unusual, except in neonates born to mothers who are receiving intravenous magnesium for preeclampsia or eclampsia (see Chapter 106).

Etiology and Pathophysiology

There is no feedback mechanism to prevent magnesium absorption from the gastrointestinal tract. Magnesium is present in high amounts in certain laxatives, enemas, cathartics used to treat drug overdoses, and antacids. It is also usually present in total parenteral nutrition, and neonates may receive high amounts transplacentally if maternal levels are elevated. Usually the kidneys excrete excessive magnesium, but this ability is diminished in patients with chronic renal failure. In addition, neonates and young infants are vulnerable to excessive magnesium ingestion because of their reduced GFR. Most pediatric cases not related to maternal hypermagnesemia occur in infants as a result of excessive use of antacids or laxatives. Mild hypermagnesemia may occur in chronic renal failure, familial hypocalciuric hypercalcemia, diabetic ketoacidosis, lithium ingestion, milk-alkali syndrome, and tumor lysis syndrome. The hypermagnesemia in diabetic ketoacidosis occurs despite significant intracellular magnesium depletion as a result of urinary losses; hypomagnesemia often occurs after insulin treatment.

Clinical Manifestations

Symptoms usually do not appear until the plasma magnesium level is >4.5 mg/dL. Hypermagnesemia inhibits acetylcholine release at the neuromuscular junction, producing hypotonia, hyporeflexia, and weakness; paralysis occurs at high concentrations. The neuromuscular effects may be exacerbated by aminoglycoside antibiotics. Direct CNS depression causes lethargy and sleepiness; infants have a poor suck. Elevated magnesium values are associated with hypotension because of vascular dilation, which also causes flushing. Hypotension can be profound at higher concentrations from a direct effect on cardiac function. ECG changes include prolonged PR, QRS, and QT intervals. Severe hypermagnesemia (>15 mg/dL) causes complete heart block and cardiac arrest. Other manifestations of hypermagnesemia include nausea, vomiting, and hypocalcemia.

Diagnosis

Except for the case of the neonate with transplacental exposure, a high index of suspicion and a good history are necessary to make the diagnosis of hypermagnesemia. Prevention is essential; magnesium-containing compounds should be used judiciously in children with renal insufficiency.

Treatment

Most patients with normal renal function rapidly clear excess magnesium. Intravenous hydration and loop diuretics can accelerate this process. In severe cases, especially in patients with underlying renal insufficiency, dialysis may be necessary. Hemodialysis works faster than peritoneal dialysis. Exchange transfusion is another option in newborn infants. Supportive care includes monitoring of cardiorespiratory status, provision of fluids, monitoring of electrolyte levels, and

the use of pressors for hypotension. In acute emergencies, especially in the context of severe neurologic or cardiac manifestations, 100 mg/kg of intravenous calcium gluconate is transiently effective.

Bibliography is available at Expert Consult.

55.6 Phosphorus

Larry A. Greenbaum

Approximately 65% of plasma phosphorus is in phospholipids, but these compounds are insoluble in acid and are not measured by clinical laboratories. It is the phosphorus content of plasma phosphate that is determined. The result is reported as either phosphate or phosphorus, although even when the term phosphate is used, it is actually the phosphorus concentration that is measured and reported. The result is that the terms phosphate and phosphorus are often used interchangeably. The term *phosphorus* is preferred when one is referring to the plasma concentration. Conversion from the units used in the United States (mg/dL) to mmol/L is straightforward (see Table 55-6).

PHOSPHORUS METABOLISM

Body Content and Physiologic Function

Most phosphorus is in bone or is intracellular, with <1% in plasma. At a physiologic pH, there are monovalent and divalent forms of phosphate because the pK of these forms is 6.8. Approximately 80% is divalent, and the remainder is monovalent at a pH of 7.4. A small percentage of plasma phosphate, approximately 15%, is protein bound. The remainder can be filtered by the glomerulus, with most existing as free phosphate and a small percentage complexed with calcium, magnesium, or sodium. Phosphate is the most plentiful intracellular anion, although the majority is part of a larger compound (ATP).

More than that of any other electrolyte, the phosphorus concentration varies with age (Table 55-8). The teleologic explanation for the high concentration during childhood is the need for phosphorus to facilitate growth. There is diurnal variation in the plasma phosphorus concentration, with the peak during sleep.

Phosphorus, as a component of ATP and other trinucleotides, is critical for cellular energy metabolism. It is necessary for cell signaling and nucleic acid synthesis, and it is a component of cell membranes and other structures. Along with calcium, phosphorus is necessary for skeletal mineralization. There is a significant need for a net positive phosphorus balance during growth, with the growing skeleton especially vulnerable to deficiency.

Intake

Phosphorus is readily available in food. Milk and milk products are the best sources of phosphorus; high concentrations are present in meat and fish. Vegetables have more phosphorus than fruits and grains. Gastrointestinal absorption of phosphorus is fairly proportional to intake, with approximately 65% of intake being absorbed, including a small amount that is secreted. Absorption, almost exclusively in the small intestine, occurs via a paracellular diffusive process and a vitamin D–regulated transcellular pathway. However, the impact of the change in phosphorus absorption caused by vitamin D is relatively small compared with the effect of variations in phosphorus intake.

Table 55-8 Serum Phosphorus Levels During Childhood

AGE	PHOSPHORUS LEVEL (mg/dL)
0-5 day	4.8-8.2
1-3 yr	3.8-6.5
4-11 yr	3.7-5.6
12-15 yr	2.9-5.4
16-19 yr	2.7-4.7

Excretion

Despite the wide variation in phosphorus absorption dictated by oral intake, excretion matches intake, except for the needs for growth. The kidney regulates phosphorus balance, which is determined by intrarenal mechanisms and hormonal actions on the nephron.

Approximately 90% of plasma phosphate is filtered at the glomerulus, although there is some variation based on plasma phosphate and calcium concentrations. There is no significant secretion of phosphate along the nephron. Resorption of phosphate occurs mostly in the proximal tubule, although a small amount can be resorbed in the distal tubule. Normally, approximately 85% of the filtered load is resorbed. A sodium-phosphate cotransporter mediates the uptake of phosphate into the cells of the proximal tubule.

The dietary phosphorus determines the amount of phosphate resorbed by the nephron. There are both acute and chronic changes in phosphate resorption that are based on intake. Many of these changes appear to be mediated by intrarenal mechanisms that are independent of regulatory hormones. Fibroblast growth factor-23 (FGF-23) inhibits renal resorption of phosphorus in the proximal tubule, and its level increases in the setting of hyperphosphatemia. FGF-23 also inhibits synthesis of calcitriol in the kidney by decreasing 1α-hydroxylase activity.

PTH, which is secreted in response to a low plasma calcium level, decreases resorption of phosphate, increasing the urinary phosphate level. This process appears to have a minimal effect during normal physiologic variation in PTH levels. However, it does have an impact in the setting of pathologic changes in PTH synthesis.

Low plasma phosphorus stimulates the 1α-hydroxylase in the kidney that converts 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D (calcitriol). Calcitriol increases intestinal absorption of phosphorus and is necessary for maximal renal resorption of phosphate. The effect of a change in calcitriol on urinary phosphate is significant only when the level of calcitriol was initially low, arguing against a role for calcitriol in nonpathologic conditions.

HYPOPHOSPHATEMIA

Because of the wide variation in normal plasma phosphorus levels, the definition of hypophosphatemia is age-dependent (see Table 55-8). The normal range reported by a laboratory may be based on adult normal values and, therefore, may be misleading in children. A serum phosphorus level of 3 mg/dL, a normal value in an adult, indicates clinically significant hypophosphatemia in an infant.

The plasma phosphorus level does not always reflect the total body stores because only 1% of phosphorus is extracellular. Thus, a child may have significant phosphorus deficiency despite a normal plasma phosphorus concentration. This situation is especially common in conditions in which there is a shift of phosphorus from the intracellular space.

Etiology and Pathophysiology

A variety of mechanisms cause hypophosphatemia (Table 55-9). A transcellular shift of phosphorus into cells occurs with processes that stimulate cellular usage of phosphorus (glycolysis). Usually, this shift causes only a minor, transient decrease in plasma phosphorus, but if intracellular phosphorus deficiency is present, the plasma phosphorus level can decrease significantly, producing symptoms of acute hypophosphatemia. Glucose infusion stimulates insulin release, leading to entry of glucose and phosphorus into the cells. Phosphorus is then used during glycolysis and other metabolic processes. A similar phenomenon can occur during the treatment of diabetic ketoacidosis, and patients with this disorder are typically phosphorus-depleted owing to urinary phosphorus losses. **Refeeding** of patients with protein-calorie malnutrition causes anabolism, which leads to significant cellular demand for phosphorus. The increased phosphorus uptake for incorporation into newly synthesized compounds containing phosphorus leads to hypophosphatemia, which can be severe and symptomatic. Refeeding hypophosphatemia occurs frequently during treatment of severe anorexia nervosa. It can occur during treatment of children with malnutrition from any cause, such as cystic fibrosis, Crohn

disease, burns, neglect, chronic infection, or famine. Hypophosphatemia usually occurs within the 1st 5 days of refeeding and is prevented by a gradual increase in nutrition with appropriate phosphorus supplementation. Total parenteral nutrition without adequate phosphorus can cause hypophosphatemia.

Phosphorus moves into the intracellular space during a respiratory alkalosis and during recovery from a respiratory acidosis. An acute decrease in the carbon dioxide concentration, by raising the intracellular pH, stimulates glycolysis, leading to intracellular use of phosphorus and hypophosphatemia. Because a metabolic alkalosis has less effect on the intracellular pH (carbon dioxide diffuses across cell membranes much faster than bicarbonate), there is minimal transcellular phosphorus movement with a metabolic alkalosis.

Tumors that grow rapidly, such as those associated with leukemia and lymphoma, may use large amounts of phosphorus, leading to hypophosphatemia. A similar phenomenon may occur during the hematopoietic reconstitution that follows bone marrow transplantation. In **hungry bone syndrome,** there is avid bone uptake of phosphorus, along with calcium and magnesium, which can produce plasma deficiency of all 3 ions. Hungry bone syndrome is most common after parathyroidectomy for hyperparathyroidism because the stimulus for bone dissolution is acutely removed, but bone synthesis continues.

Nutritional phosphorus deficiency is unusual because most foods contain phosphorus. However, infants are especially susceptible because of their high demand for phosphorus to support growth, especially of the skeleton. Very-low-birthweight infants have particularly rapid skeletal growth, and phosphorus deficiency and rickets may develop if they are fed human milk or formula for term infants. There is also a relative deficiency of calcium. The provision of additional calcium and phosphorus, using breast milk fortifier or special premature infant formula, prevents this complication. Phosphorus deficiency, sometimes with concomitant calcium and vitamin D deficiencies, occurs in infants who are not given enough milk or who receive a milk substitute that is nutritionally inadequate.

Antacids containing aluminum hydroxide, such as Maalox and Mylanta, bind dietary phosphorus and secreted phosphorus, preventing absorption. This process can cause phosphorus deficiency and rickets in growing children. A similar mechanism causes hypophosphatemia in patients who are overtreated for hyperphosphatemia with phosphorus binders. In children with kidney failure, the addition of dialysis to phosphorus binders increases the risk of iatrogenic hypophosphatemia in these normally hyperphosphatemic patients. This complication, which is more common in infants, can worsen renal osteodystrophy.

Excessive renal losses of phosphorus occur in a variety of inherited and acquired disorders. Because PTH inhibits the resorption of phosphorus in the proximal tubule, **hyperparathyroidism** causes hypophosphatemia (see Chapter 573). The dominant clinical manifestation, however, is hypercalcemia, and the hypophosphatemia is usually asymptomatic. The phosphorus level in hyperparathyroidism is not extremely low, and there is no continued loss of phosphorus because a new steady state is achieved at the lower plasma phosphorus level. Renal excretion, therefore, does not exceed intake over the long-term. There are occasional malignancies that produce PTH-related peptide, which has the same actions as PTH and causes hypophosphatemia and hypercalcemia.

A variety of diseases cause renal phosphate wasting, hypophosphatemia, and rickets resulting from excess FGF-23 (see Chapter 51). These disorders include **X-linked hypophosphatemic rickets, tumor-induced osteomalacia**, **autosomal dominant hypophosphatemic rickets,** and **autosomal recessive hypophosphatemic rickets**. Heterozygous mutations in a phosphate transporter or a regulator of proximal tubule phosphate transport cause hypophosphatemia, osteoporosis, and nephrolithiasis (**hypophosphatemic nephrolithiasis/osteoporosis type 1 or 2**).

Fanconi syndrome is a generalized defect in the proximal tubule leading to urinary wasting of bicarbonate, phosphorus, amino acids, uric acid, and glucose (see Chapter 529). The clinical sequelae are a result of the metabolic acidosis and hypophosphatemia. In children, an underlying genetic disease, most commonly cystinosis, often causes Fanconi syndrome, but it can be secondary to a variety of toxins and acquired diseases. Some patients have incomplete Fanconi syndrome, and phosphorus wasting may be one of the manifestations.

Dent disease, an X-linked disorder, can cause renal phosphorus wasting and hypophosphatemia, although the latter is not present in most cases. Other possible manifestations of Dent disease include tubular proteinuria, hypercalciuria, nephrolithiasis, rickets, and chronic renal failure. Dent disease may be secondary to mutations in a gene that encodes a chloride channel or the OCRL1 gene, which may also cause Lowe syndrome (see Chapter 529.1). **Hypophosphatemic rickets with hypercalciuria** is a rare disorder, principally described in kindreds from the Middle East. Mutations in a sodium-phosphate cotransporter cause hypophosphatemia in this disorder, and complications may include nephrolithiasis and osteoporosis; the disorder is autosomal dominant.

Metabolic acidosis inhibits resorption of phosphorus in the proximal tubule. In addition, metabolic acidosis causes a transcellular shift of phosphorus out of cells because of intracellular catabolism. This

released phosphorus is subsequently lost in the urine, leading to significant phosphorus depletion, even though the plasma phosphorus level may be normal. This classically occurs in diabetic ketoacidosis in which renal phosphorus loss is further increased by the osmotic diuresis. With correction of the metabolic acidosis and the administration of insulin, both of which cause a transcellular movement of phosphorus into the cells, there is a marked decrease in the plasma phosphorus level.

Volume expansion from any cause, such as hyperaldosteronism or SIADH, inhibits resorption of phosphorus in the proximal tubule. This effect also occurs with high rates of intravenous fluids. Thiazide and loop diuretics can increase renal phosphorus excretion, but the increase is seldom clinically significant. Glycosuria and glucocorticoids inhibit renal conservation of phosphorus. Hypophosphatemia is common after kidney transplantation as a result of urinary phosphorus losses. Possible explanations include preexisting secondary hyperparathyroidism from chronic renal failure, glucocorticoid therapy, and upregulation of FGF-23 before transplantation. The hypophosphatemia usually resolves in a few months.

Both acquired and genetic causes of **vitamin D deficiency** are associated with hypophosphatemia (see Chapter 51). The pathogenesis is multifactorial. Vitamin D deficiency, by impairing intestinal calcium absorption, causes secondary hyperparathyroidism that leads to increased urinary phosphorus wasting. An absence of vitamin D decreases intestinal absorption of phosphorus and directly decreases renal resorption of phosphorus. The dominant clinical manifestation is rickets, although some patients have muscle weakness that may be related to phosphorus deficiency.

Alcoholism is the most common cause of severe hypophosphatemia in adults. Fortunately, many of the risk factors that predispose adult alcoholics to hypophosphatemia are not usually present in adolescents (malnutrition, antacid abuse, recurrent episodes of diabetic ketoacidosis). Hypophosphatemia often occurs in sepsis, but the mechanism is not clear. Aggressive, protracted hemodialysis, as might be used for the treatment of methanol or ethylene glycol ingestion, can cause hypophosphatemia.

Clinical Manifestations

There are acute and chronic manifestations of hypophosphatemia. Rickets occurs in children with long-term phosphorus deficiency. The clinical features of rickets are described in Chapter 51.

Severe hypophosphatemia, typically at levels <1.0-1.5 mg/dL, may affect every organ in the body because phosphorus has a critical role in maintaining adequate cellular energy. Phosphorus is a component of ATP and is necessary for glycolysis. With inadequate phosphorus, red blood cell 2,3-diphosphoglycerate levels decrease, impairing release of oxygen to the tissues. Severe hypophosphatemia can cause hemolysis and dysfunction of white blood cells. Chronic hypophosphatemia causes proximal muscle weakness and atrophy. In the intensive care unit, phosphorus deficiency may slow weaning from mechanical ventilation or cause acute respiratory failure. **Rhabdomyolysis** is the most common complication of acute hypophosphatemia, usually in the setting of an acute transcellular shift of phosphorus into cells in a child with chronic phosphorus depletion (anorexia nervosa). The rhabdomyolysis is actually somewhat protective, in that there is cellular release of phosphorus. Other manifestations of severe hypophosphatemia include cardiac dysfunction and neurologic symptoms, such as tremor, paresthesia, ataxia, seizures, delirium, and coma.

Diagnosis

The history and basic laboratory evaluation often suggest the etiology of hypophosphatemia. The history should investigate nutrition, medications, and familial disease. Hypophosphatemia and rickets in an otherwise healthy young child suggests a genetic defect in renal phosphorus conservation, Fanconi syndrome, inappropriate use of antacids, poor nutrition, vitamin D deficiency, or a genetic defect in vitamin D metabolism. The patient with Fanconi syndrome usually has metabolic acidosis, glycosuria, aminoaciduria, and a low plasma uric acid level. Measurement of 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D, calcium, and PTH differentiates among the various vitamin D deficiency disorders and primary renal phosphate wasting (see Chapter 51). Hyperparathyroidism is easily distinguished by the presence of elevated plasma PTH and calcium values.

Treatment

The plasma phosphorus level, the presence of symptoms, the likelihood of chronic depletion, and the presence of ongoing losses dictate the approach to therapy. Mild hypophosphatemia does not require treatment unless the clinical situation suggests that chronic phosphorus depletion is present or that losses are ongoing. Oral phosphorus can cause diarrhea, so the doses should be divided. Intravenous therapy is effective in patients who have severe deficiency or who cannot tolerate oral medications. Intravenous phosphorus is available as either sodium phosphate or potassium phosphate, with the choice usually based on the patient's plasma potassium level. Starting doses are 0.08-0.16 mmol/kg over 6 hr. The oral preparations of phosphorus are available with various ratios of sodium and potassium. This is an important consideration because some patients may not tolerate the potassium load, whereas supplemental potassium may be helpful in some diseases, such as Fanconi syndrome and malnutrition. Oral maintenance dosages are 2-3 mmol/kg/day in divided doses.

Increasing dietary phosphorus is the only intervention needed in infants with inadequate intake. Other patients may also benefit from increased dietary phosphorus, usually from dairy products. Phosphorus-binding antacids should be discontinued in patients with hypophosphatemia. Certain diseases require specific therapy (see Chapter 51).

HYPERPHOSPHATEMIA

Etiology and Pathophysiology

Renal insufficiency is the most common cause of hyperphosphatemia, with the severity proportional to the degree of kidney impairment (see Chapter 535). This occurs because gastrointestinal absorption of the large dietary intake of phosphorus is unregulated, and the kidneys normally excrete this phosphorus. As renal function deteriorates, increased excretion of phosphorus is able to compensate. When kidney function is <30% of normal, hyperphosphatemia usually develops, although the time of its development may vary considerably according to dietary phosphorus absorption. Many of the other causes of hyperphosphatemia are more likely to develop in the setting of renal insufficiency (Table 55-10).

Cellular content of phosphorus is high relative to plasma phosphorus, and cell lysis can release substantial phosphorus. This is the etiology of hyperphosphatemia in **tumor lysis syndrome, rhabdomyolysis,** and **acute hemolysis.** These disorders cause concomitant potassium

release and the risk of hyperkalemia. Additional features of tumor lysis and rhabdomyolysis are hyperuricemia and hypocalcemia, whereas indirect hyperbilirubinemia and elevated lactate dehydrogenase values are often present with hemolysis. An elevated CPK level is suggestive of rhabdomyolysis. During lactic acidosis or diabetic ketoacidosis, usage of phosphorus by cells decreases, and phosphorus shifts into the extracellular space. This problem reverses when the underlying problem is corrected, and especially with diabetic ketoacidosis, patients subsequently become hypophosphatemic as a result of previous renal phosphorus loss.

Excessive intake of phosphorus is especially dangerous in children with renal insufficiency. Neonates are at risk because renal function is normally reduced during the 1st few months of life. In addition, they may erroneously be given doses of phosphorus that are meant for an older child or adult. In infants fed cow's milk, which has higher phosphorus content than breast milk or formula, hyperphosphatemia may develop. **Fleet Enema** has a high amount of phosphorus that can be absorbed, especially in the patient with an ileus. Infants and children with Hirschsprung disease are especially vulnerable. There is often associated hypernatremia owing to sodium absorption and water loss from diarrhea. Sodium phosphorus laxatives may cause hyperphosphatemia if the dose is excessive or if renal insufficiency is present. Hyperphosphatemia occurs in children who receive overly aggressive treatment for hypophosphatemia. Vitamin D intoxication causes excessive gastrointestinal absorption of both calcium and phosphorus, and the suppression of PTH by hypercalcemia decreases renal phosphorus excretion.

The absence of PTH in **hypoparathyroidism** or PTH responsiveness in **pseudohypoparathyroidism** causes hyperphosphatemia because of increased resorption of phosphorus in the proximal tubule of the kidney (see Chapters 571 and 572). The associated hypocalcemia is responsible for the clinical symptoms. The hyperphosphatemia in hyperthyroidism or acromegaly is usually minor. It is secondary to increased resorption of phosphorus in the proximal tubule from the actions of thyroxine or growth hormone. Excessive thyroxine can also cause bone resorption, which may contribute to the hyperphosphatemia and cause hypercalcemia. Patients with **familial tumoral calcinosis,** a rare autosomal recessive disorder, have hyperphosphatemia as a result of decreased renal phosphate excretion and heterotopic calcifications. The disease may be secondary to mutations in the genes for a glycosyltransferase, the phosphatonin FGF-23, or the gene for Klotho, which encodes the coreceptor for FGF-23.

Clinical Manifestations

The principal clinical consequences of hyperphosphatemia are hypocalcemia and systemic calcification. The hypocalcemia is probably due to tissue deposition of calcium-phosphorus salt, inhibition of 1,25-dihydroxyvitamin D production, and decreased bone resorption. Symptomatic hypocalcemia is most likely to occur when the phosphorus level increases rapidly or when diseases predisposing to hypocalcemia are present (chronic renal failure, rhabdomyolysis). Systemic calcification occurs because the solubility of phosphorus and calcium in the plasma is exceeded. This is believed to happen when plasma calcium × plasma phosphorus, both measured in mg/dL, is >70. Clinically, this condition is often apparent in the conjunctiva, where it manifests as a foreign-body feeling, erythema, and injection. More ominous manifestations are hypoxia from pulmonary calcification and renal failure from nephrocalcinosis.

Diagnosis

Plasma creatinine and BUN levels should be assessed in any patient with hyperphosphatemia. The history should focus on intake of phosphorus and the presence of chronic diseases that may cause hyperphosphatemia. Measurement of potassium, uric acid, calcium, lactate dehydrogenase, bilirubin, hemoglobin, and CPK may be indicated if rhabdomyolysis, tumor lysis, or hemolysis is suspected. With mild hyperphosphatemia and significant hypocalcemia, measurement of the serum PTH level distinguishes between hypoparathyroidism and pseudohypoparathyroidism.

Treatment

The treatment of acute hyperphosphatemia depends on its severity and etiology. Mild hyperphosphatemia in a patient with reasonable renal function spontaneously resolves; the resolution can be accelerated by dietary phosphorus restriction. If kidney function is not impaired, then intravenous fluids can enhance renal phosphorus excretion. For more significant hyperphosphatemia or a situation such as tumor lysis or rhabdomyolysis, in which endogenous phosphorus generation is likely to continue, addition of an oral phosphorus binder prevents absorption of dietary phosphorus and can remove phosphorus from the body by binding what is normally secreted and absorbed by the gastrointestinal tract. Phosphorus binders are most effective when given with food. Binders containing aluminum hydroxide are especially efficient, but calcium carbonate is an effective alternative and may be preferred if there is a need to treat concomitant hypocalcemia. Preservation of renal function, for example with high urine flow in rhabdomyolysis or tumor lysis, is an important adjunct because it will permit continued excretion of phosphorus. If the hyperphosphatemia is not responding to conservative management, especially if renal insufficiency is supervening, then dialysis may be necessary to increase phosphorus removal.

Dietary phosphorus restriction is necessary for diseases causing chronic hyperphosphatemia. However, such diets are often difficult to follow, given the abundance of phosphorus in a variety of foods. Dietary restriction is often sufficient in conditions such as hypoparathyroidism and mild renal insufficiency. For more problematic hyperphosphatemia, such as with moderate renal insufficiency and end-stage renal disease, phosphorus binders are usually necessary. They include calcium carbonate, calcium acetate, sevelamer, and lanthanum. Aluminum-containing phosphorus binders are no longer used in chronic renal insufficiency because of the risk of aluminum toxicity. Dialysis directly removes phosphorus from the blood in patients with end-stage renal disease, but it is only an adjunct to dietary restriction and phosphorus binders, in that elimination of phosphorus by dialysis is not efficient enough to keep up with normal dietary intake.

Bibliography is available at Expert Consult.

55.7 Acid–Base Balance

Larry A. Greenbaum

ACID–BASE PHYSIOLOGY

Introduction and Terminology

Chronic, mild derangements in acid–base status may interfere with normal growth and development, whereas acute, severe changes in pH can be fatal. Control of acid–base balance depends on the kidneys, the lungs, and intracellular and extracellular buffers.

A normal pH is 7.35-7.45. There is an inverse relationship between the pH and the hydrogen ion concentration. At a pH of 7.40, the hydrogen ion concentration is 40 nmol/L. A normal serum sodium concentration, 140 mEq/L, is 1 million times higher. Maintaining a normal pH is necessary because hydrogen ions are highly reactive and are especially likely to combine with proteins, altering their function.

An **acid** is a substance that releases ("donates") a hydrogen ion (H^+). A base is a substance that accepts a hydrogen ion. An acid (HA) can dissociate into a hydrogen ion and a conjugate base (A^-), as follows:

$$HA \leftrightarrow H^+ + A^-$$

A strong acid is highly dissociated, so in this reaction, there is little HA. A weak acid is poorly dissociated; not all of the hydrogen ions are released from HA. A^- acts as a base when the reaction moves to the left. These reactions are in equilibrium. When HA is added to the system, there is dissociation of some HA until the concentrations of H^+ and A^- increase enough that a new equilibrium is reached. Addition of hydrogen ions causes a decrease in A^- and an increase in HA. Addition of A^- causes a decrease in hydrogen ions and an increase in HA.

Buffers are substances that attenuate the change in pH that occurs when acids or bases are added to the body. Given the extremely low

concentration of hydrogen ions in the body at physiologic pH, without buffers a small amount of hydrogen ions could cause a dramatic decline in the pH. Buffers prevent the decrease in pH by binding the added hydrogen ions, as follows:

$$A^- + H^+ \rightarrow HA$$

The increase in hydrogen ion concentration drives this reaction to the right. Similarly, when base is added to the body, buffers prevent the pH from increasing by releasing hydrogen ions, as follows:

$$HA \rightarrow A^- + H^+$$

The best buffers are weak acids and bases. This is because a buffer works best when it is 50% dissociated (half HA and half A^-). The pH at which a buffer is 50% dissociated is its pK (ionization constant of acid). The best physiologic buffers have a pK close to 7.40. The concentration of a buffer and its pK determine the buffer's effectiveness (buffering capacity). When the pH is lower than the pK of a buffer, there is more HA than A^-. When the pH is higher than the pK, there is more A^- than HA.

Physiologic Buffers

The bicarbonate and nonbicarbonate buffers protect the body against major changes in pH. The **bicarbonate buffer system** is routinely monitored clinically. The bicarbonate buffer system is based on the relationship between carbon dioxide (CO_2) and bicarbonate (HCO_3^-):

$$CO_2 + H_2O \leftrightarrow H^+ + HCO_3^-$$

Carbon dioxide acts as an acid in that, after combining with water, it releases a hydrogen ion; bicarbonate acts as its conjugate base in that it accepts a hydrogen ion. The pK of this reaction is 6.1. The Henderson-Hasselbalch equation expresses the relationship among pH, pK, and the concentrations of an acid and its conjugate base. This relationship is valid for any buffer. The Henderson-Hasselbalch equation for bicarbonate and carbon dioxide is as follows:

$$pH = 6.1 + \log[HCO_3^-]/[CO_2]$$

The Henderson-Hasselbalch equation for the bicarbonate buffer system has 3 variables: pH, $[HCO_3^-]$, and $[CO_2]$. Thus, if any 2 of these variables are known, it is possible to calculate the third. When one is using the Henderson-Hasselbalch equation, it is important that carbon dioxide and bicarbonate have the same units. Carbon dioxide is reported clinically as mm Hg and must be multiplied by its solubility constant, 0.03 mmol/L/mm Hg, before the Henderson-Hasselbalch equation can be used. Mathematical manipulation of the Henderson-Hasselbalch equation produces the following relationship:

$$[H^+] = 24 \times P_{CO_2}/(HCO_3^-)$$

At a normal hydrogen ion concentration of 40 nmol (pH 7.40), the partial pressure of carbon dioxide (P_{CO_2}), which is expressed as mm Hg in this equation, is 40 when the bicarbonate concentration is 24 mEq/L. This equation emphasizes that the hydrogen ion concentration, and hence pH, can be determined by the ratio of P_{CO_2} and the bicarbonate concentration.

The bicarbonate buffer system is very effective as a result of the high concentration of bicarbonate in the body (24 mEq/L) and the fact that it is an open system. The remaining body buffers are in a closed system. The bicarbonate buffer system is an open system because the lungs increase carbon dioxide excretion when the blood carbon dioxide concentration increases. When acid is added to the body, the following reaction occurs:

$$H^+ + HCO_3^- \rightarrow CO_2 + H_2O$$

In a closed system, the CO_2 would increase. The higher CO_2 concentration would lead to an increase in the reverse reaction:

$$CO_2 + H_2O \rightarrow H^+ + HCO_3^-$$

This would increase the concentration of hydrogen ions, limiting the buffering capacity of bicarbonate. However, because the lungs excrete the excess carbon dioxide, the reverse reaction does not increase; this fact enhances the buffering capacity of bicarbonate. The same principle holds with the addition of base, because the lungs decrease carbon dioxide excretion and prevent the level of carbon dioxide from falling. The lack of change in carbon dioxide concentration dramatically increases the buffering capacity of bicarbonate.

The **nonbicarbonate buffers** include proteins, phosphate, and bone. Protein buffers consist of extracellular proteins, mostly albumin and intracellular proteins, including hemoglobin. Proteins are effective buffers, largely because of the presence of the amino acid histidine, which has a side chain that can bind or release hydrogen ions. The pK of histidine varies slightly, depending on its position in the protein molecule, but its average pK is approximately 6.5. This is close enough to a normal pH (7.4) to make histidine an effective buffer. Hemoglobin and albumin have 34 and 16 histidine molecules, respectively.

Phosphate can bind up to 3 hydrogen molecules, so it can exist as PO_4^{3-}, HPO_4^{2-}, $H_2PO_4^{1-}$, or H_3PO_4. However, at a physiologic pH, most phosphate exists as either HPO_4^{2-} or $H_2PO_4^{1-}$. $H_2PO_4^{1-}$ is an acid, and HPO_4^{2-} is its conjugate base:

$$H_2PO_4^{1-} \leftrightarrow H^+ + HPO_4^{2-}$$

The pK of this reaction is 6.8, making phosphate an effective buffer. The concentration of phosphate in the extracellular space is relatively low, limiting the overall buffering capacity of phosphate; it is less important than albumin. However, phosphate is found at a much higher concentration in the urine, where it is an important buffer. In the intracellular space, most phosphate is covalently bound to organic molecules (ATP), but it still serves as an effective buffer.

Bone is an important buffer. Bone is basic—it is composed of compounds such as sodium bicarbonate and calcium carbonate—and thus, dissolution of bone releases base. This release can buffer an acid load, although at the expense of bone density, if it occurs over an extended period. In contrast, bone formation, by consuming base, helps buffer excess base.

Clinically, we measure the extracellular pH, but it is the intracellular pH that affects cell function. Measurement of the intracellular pH is unnecessary because changes in the intracellular pH parallel the changes in the extracellular pH. However, the change in the intracellular pH tends to be less than the change in the extracellular pH because of the greater buffering capacity in the intracellular space.

NORMAL ACID–BASE BALANCE

The lungs and kidneys maintain a normal acid–base balance. Carbon dioxide generated during normal metabolism is a weak acid. The lungs prevent an increase in the P_{CO_2} in the blood by excreting the CO_2 that the body produces. CO_2 production varies according to the body's metabolic needs, increasing with physical activity. The rapid pulmonary response to changes in the CO_2 concentration occurs via central sensing of the P_{CO_2} and a subsequent increase or decrease in ventilation to maintain a normal P_{CO_2} (35-45 mm Hg). An increase in ventilation decreases the P_{CO_2}, and a decrease in ventilation increases the P_{CO_2}.

The kidneys excrete endogenous acid. An adult normally produces approximately 1-2 mEq/kg/24 hr of hydrogen ions. Children normally produce 2-3 mEq/kg/24 hr of hydrogen ions. The 3 principal sources of hydrogen ions are dietary protein metabolism, incomplete metabolism of carbohydrates and fat, and stool losses of bicarbonate. Because metabolism of protein generates hydrogen ions, endogenous acid production varies with protein intake. The complete oxidation of carbohydrates or fats to carbon dioxide and water does not generate hydrogen ions; the lungs remove the carbon dioxide. However, incomplete metabolism of carbohydrates or fats produces hydrogen ions. Incomplete glucose metabolism can produce lactic acid, and incomplete triglyceride metabolism can produce keto acids, such as β-hydroxybutyric acid and acetoacetic acid. There is always some baseline incomplete metabolism that contributes to endogenous acid production. This factor increases in pathologic conditions, such as lactic acidosis and diabetic ketoacidosis. Stool loss of bicarbonate is the third major source of endogenous acid production. The stomach secretes hydrogen ions,

but most of the remainder of the gastrointestinal tract secretes bicarbonate, and the net effect is a loss of bicarbonate from the body. To secrete bicarbonate, the cells of the intestine produce hydrogen ions that are released into the bloodstream. For each bicarbonate molecule lost in the stool, the body gains 1 hydrogen ion. This source of endogenous acid production is normally minimal but may increase dramatically in a patient with diarrhea.

The hydrogen ions formed from endogenous acid production are neutralized by bicarbonate, potentially causing the bicarbonate concentration to decrease. The kidneys regenerate this bicarbonate by secreting hydrogen ions. The lungs cannot regenerate bicarbonate, even though loss of carbon dioxide lowers the hydrogen ion concentration, as shown in the following reaction:

$$H^+ + HCO_3^- \rightarrow CO_2 + H_2O$$

A decrease in CO_2 concentration causes the reaction to move to the right, which decreases the hydrogen ion concentration, but it also lowers the bicarbonate concentration. During a metabolic acidosis, hyperventilation can lower the CO_2 concentration, decrease the hydrogen ion concentration, and thus increase the pH. The underlying metabolic acidosis is still present. Similarly, the kidneys cannot correct an abnormally high CO_2 concentration, as shown in the following reaction:

$$H^+ + HCO_3^- \rightarrow CO_2 + H_2O$$

An increase in the bicarbonate concentration also causes the reaction to move to the right, which increases the CO_2 concentration while simultaneously decreasing the hydrogen ion concentration. During a respiratory acidosis, increased renal generation of bicarbonate can decrease the hydrogen ion concentration and increase the pH, but cannot repair the respiratory acidosis. Both the lungs and the kidneys can affect the hydrogen ion concentration and hence the pH. However, only the lungs can regulate the CO_2 concentration, and only the kidneys can regulate the bicarbonate concentration.

Renal Mechanisms

The kidneys regulate the serum bicarbonate concentration by modifying acid excretion in the urine. This requires a 2-step process. First, the renal tubules resorb the bicarbonate that is filtered at the glomerulus. Second, there is tubular secretion of hydrogen ions. The urinary excretion of hydrogen ions generates bicarbonate that neutralizes endogenous acid production. The tubular actions necessary for renal acid excretion occur throughout the nephron (Fig. 55-6).

The resorption of filtered bicarbonate is a necessary first step in renal regulation of the acid–base balance. A normal adult has a GFR of approximately 180 L/24 hr. This fluid enters the Bowman space with a bicarbonate concentration that is essentially identical to the plasma concentration, normally 24 mEq/L. Multiplying 180 L by 24 mEq/L indicates that >4,000 mEq of bicarbonate enters the Bowman space each day. This bicarbonate, if not reclaimed along the nephron, would be lost in the urine and would cause a profound metabolic acidosis.

The proximal tubule reclaims approximately 85% of the filtered bicarbonate (Fig. 55-7). The final 15% is reclaimed beyond the proximal tubule, mostly in the ascending limb of the loop of Henle. Bicarbonate molecules are not transported from the tubular fluid into the cells of the proximal tubule. Rather, hydrogen ions are secreted into the tubular fluid, leading to conversion of filtered bicarbonate into CO_2 and water. The secretion of hydrogen ions by the cells of the proximal tubule is coupled to generation of intracellular bicarbonate, which is transported across the basolateral membrane of the proximal tubule cell and enters the capillaries. The bicarbonate produced in the cell replaces the bicarbonate filtered at the glomerulus.

Increased bicarbonate resorption by the cells of the proximal tubule—the result of increased hydrogen ion secretion—occurs in a variety of clinical situations. Volume depletion increases bicarbonate resorption. This is partially mediated by activation of the renin–angiotensin system; angiotensin II increases bicarbonate resorption. Increased bicarbonate resorption in the proximal tubule is one of the mechanisms that accounts for the metabolic alkalosis that may occur in some patients with volume depletion. Other stimuli that increase bicarbonate resorption include hypokalemia and an increased P_{CO_2}. This partially explains the observations that hypokalemia causes a metabolic alkalosis and that a respiratory acidosis leads to a compensatory increase in serum bicarbonate concentration.

Stimuli that decrease bicarbonate resorption in the proximal tubule may cause a decrease in the serum bicarbonate concentration. A decrease in the P_{CO_2} (respiratory alkalosis) decreases proximal tubule bicarbonate resorption, partially mediating the decrease in serum bicarbonate concentration that compensates for a respiratory alkalosis.

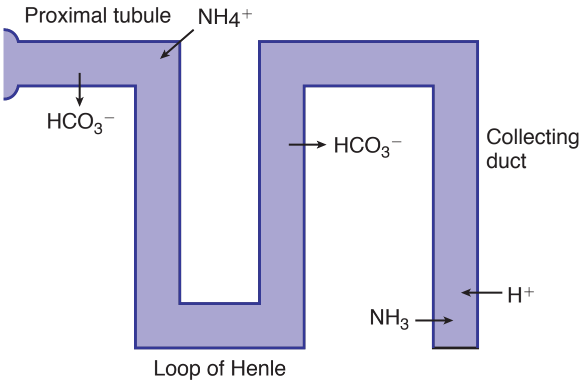

Figure 55-6 Tubular sites involved in acid–base balance. The proximal tubule is the site where most filtered bicarbonate is reclaimed, even though other sites along the nephron, especially the thick ascending limb of the loop of Henle, resorb some of the filtered bicarbonate. The collecting duct is the principal location for the hydrogen ion secretion that acidifies the urine. The proximal tubule generates the ammonia that serves as a urinary buffer in the collecting duct.

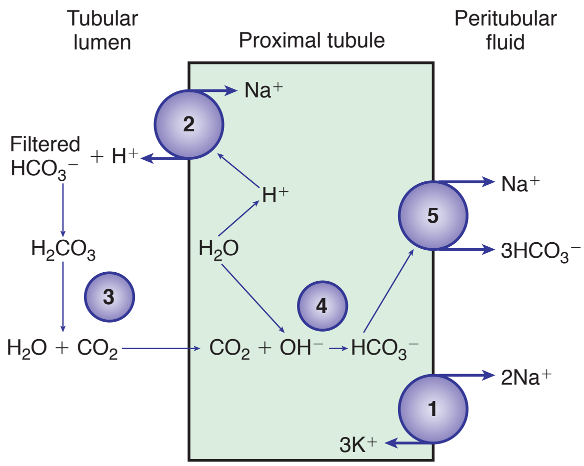

Figure 55-7 Resorption of filtered bicarbonate in the proximal tubule. The Na^+,K^+-ATPase *(1)* excretes sodium across the basolateral cell membrane, maintaining a low intracellular sodium concentration. The low intracellular sodium concentration provides the energy for the Na^+,H^+ antiporter *(2)*, which exchanges sodium from the tubular lumen for intracellular hydrogen ions. The hydrogen ions that are secreted into the tubular lumen then combine with filtered bicarbonate to generate carbonic acid. CO_2 and water are produced from carbonic acid (H_2CO_3). This reaction is catalyzed by luminal carbonic anhydrase *(3)*. CO_2 diffuses into the cell and combines with OH^- ions to generate bicarbonate. This reaction is catalyzed by an intracellular carbonic anhydrase *(4)*. The dissociation of water generates an OH^- ion and an H^+ ion. The Na^+,H^+ antiporter *(2)* secretes the hydrogen ions. Bicarbonate ions cross the basolateral membrane and enter the blood via the $3HCO_3^-/1Na^+$ cotransporter *(5)*. The energy for the $3HCO_3^-/1Na^+$ cotransporter comes from the negatively charged cell interior, which makes it electrically favorable to transport a net negative charge (i.e., 3 bicarbonates and only 1 sodium) out of the cell.

PTH decreases proximal tubule bicarbonate resorption; hyperparathyroidism may cause a mild metabolic acidosis. A variety of medications and diseases cause a metabolic acidosis by impairing bicarbonate resorption in the proximal tubule. Examples are the medication acetazolamide, which directly inhibits carbonic anhydrase, and the many disorders that cause proximal RTA (see Chapter 329).

After reclaiming filtered bicarbonate, the kidneys perform the second step in renal acid–base handling, the excretion of the acid created by endogenous acid production. Excretion of acid occurs mostly in the collecting duct, with a small role for the distal tubule.

Along with secretion of hydrogen ions by the tubular cells lining the collecting duct, adequate excretion of endogenous acid requires the presence of urinary buffers. The hydrogen pumps in the collecting duct cannot lower the urine pH below 4.5. The hydrogen ion concentration at pH 4.5 is <0.04 mEq/L; it would require >25 L of water with a pH of 4.5 to excrete 1 mEq of hydrogen ions. A 10-kg child, with an endogenous acid production of 20 mEq of hydrogen ions each day, would need to have a daily urinary output of >500 L without the presence of urinary buffers. As in the blood, buffers in the urine attenuate the decrease in pH that occurs with the addition of hydrogen ions. The 2 principal urinary buffers are phosphate and ammonia.

Urinary phosphate is proportional to dietary intake. Whereas most of the phosphate filtered at the glomerulus is resorbed in the proximal tubule, the urinary phosphate concentration is usually much greater than the serum phosphate concentration. This arrangement allows phosphate to serve as an effective buffer via the following reaction:

$$H^+ + HPO_4^{2-} \rightarrow H_2PO_4^{1-}$$

The pK of this reaction is 6.8, making phosphate an effective buffer as the urinary pH decreases from 7.0 to 5.0 within the collecting duct. Although phosphate is an effective buffer, its buffering capacity is limited by its concentration; there is no mechanism for increasing urinary phosphate excretion in response to changes in acid–base status.

In contrast, ammonia production can be modified, allowing for regulation of acid excretion. The buffering capacity of ammonia is based on the reaction of ammonia with hydrogen ions to form ammonium:

$$NH_3 + H^+ \rightarrow NH_4^+$$

The cells of the proximal tubule are the source of the excreted ammonia, mostly through metabolism of glutamine via the following reactions:

$$\text{Glutamine} \rightarrow NH_4^+ + \text{glutamate}^-$$

$$\text{Glutamine}^- \rightarrow NH_4^+ + \alpha\text{-ketoglutarate}^{2-}$$

The metabolism of glutamine generates 2 ammonium ions. In addition, the metabolism of α-ketoglutarate generates 2 bicarbonate molecules. The ammonium ions are secreted into the lumen of the proximal tubule, whereas the bicarbonate molecules exit the proximal tubule cells via the basolateral $Na^+,3HCO_3^-$ cotransporter (see Fig. 55-6). This arrangement would seem to accomplish the goal of excreting hydrogen ions (as NH_4^+) and regenerating bicarbonate molecules. However, the ammonium ions secreted in the proximal tubule do not remain within the tubular lumen. Cells of the TAL of the loop of Henle resorb the ammonium ions. The result is that there is a high medullary interstitial concentration of ammonia, but the tubular fluid entering the collecting duct does not have significant amounts of ammonium ions. Moreover, the hydrogen ions that were secreted with ammonia, as ammonium ions, in the proximal tubule enter the bloodstream, canceling the effect of the bicarbonate generated in the proximal tubule. The excretion of ammonium ions, and hence of hydrogen ions, depends on the cells of the collecting duct.

The cells of the collecting duct secrete hydrogen ions and regenerate bicarbonate, which is returned to the bloodstream (Fig. 55-8). This bicarbonate neutralizes endogenous acid production. Phosphate and ammonia buffer the hydrogen ions secreted by the collecting duct. Ammonia is an effective buffer because of the high concentrations in the medullary interstitium and because the cells of the collecting duct are permeable to ammonia but not to ammonium. As ammonia

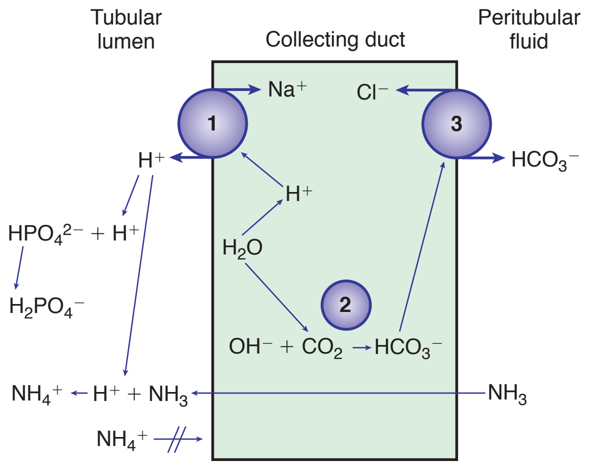

Figure 55-8 **Secretion of hydrogen ions in the collecting duct.** The dissociation of water generates an OH^- ion and an H^+ ion. The H^+-ATPase *(1)* secretes hydrogen ions into the tubular lumen. Bicarbonate is formed when an OH^- ion combines with CO_2 in a reaction mediated by carbonic anhydrase *(2)*. Bicarbonate ions cross the basolateral membrane and enter the blood via the HCO_3^-/Cl^- exchanger *(3)*. The hydrogen ions in the tubular lumen are buffered by phosphate and ammonia (NH_3). NH_3 can diffuse from the peritubular fluid into the tubular lumen, but ammonium (NH_4^+) cannot pass through the cells of the collecting duct.

diffuses into the lumen of the collecting duct, the low urine pH causes almost all of the ammonia to be converted into ammonium. This process maintains a low luminal ammonia concentration. Because the luminal pH is lower than the pH in the medullary interstitium, there is a higher concentration of ammonia within the medullary interstitium than in the tubular lumen, favoring movement of ammonia into the tubular lumen. Even though the concentration of ammonium in the tubular lumen is higher than in the interstitium, the cells of the collecting duct are impermeable to ammonium, preventing back-diffusion of ammonium out of the tubular lumen and permitting ammonia to be an effective buffer. The kidneys adjust hydrogen ion excretion according to physiologic needs. There is variation in endogenous acid production, largely a result of diet and pathophysiologic stresses, such as diarrheal losses of bicarbonate, which increase the need for acid excretion. Hydrogen excretion is increased by upregulation of hydrogen ion secretion in the collecting duct, causing the pH of the urine to decrease. This response is fairly prompt, occurring within hours of an acid load, but it is limited by the buffering capacity of the urine; the hydrogen pumps in the collecting duct cannot lower the pH to <4.5. A more significant increase in acid excretion requires upregulation of ammonia production by the proximal tubule so that more ammonia is available to serve as a buffer in the tubular lumen of the collecting duct. This response to a low serum pH reaches its maximum within 5-6 days; ammonia excretion can increase approximately 10-fold over the baseline value.

Acid excretion by the collecting duct increases in a number of different clinical situations. The extracellular pH is the most important regulator of renal acid excretion. A decrease in the extracellular pH from either a respiratory or a metabolic acidosis causes an increase in renal acid excretion. Aldosterone stimulates hydrogen ion excretion in the collecting duct, causing an increase in the serum bicarbonate concentration. This explains the metabolic alkalosis that occurs with primary hyperaldosteronism or secondary hyperaldosteronism caused by volume depletion. Hypokalemia increases acid secretion, by both stimulating ammonia production in the proximal tubule and increasing hydrogen ion secretion in the collecting duct. Hypokalemia therefore tends to produce a metabolic alkalosis. Hyperkalemia has the opposite effects, which may cause a metabolic acidosis.

In patients with an increased pH, the kidney has 2 principal mechanisms for correcting the problem. First, less bicarbonate is resorbed in the proximal tubule, leading to an increase in urinary bicarbonate

losses. Second, in a limited number of specialized cells, the process for secretion of hydrogen ions by the collecting duct (see Fig. 55-8) can be reversed, leading to secretion of bicarbonate into the tubular lumen and secretion of hydrogen ions into the peritubular fluid, where they enter the bloodstream.

CLINICAL ASSESSMENT OF ACID–BASE DISORDERS

The following equation, a rearrangement of the Henderson-Hasselbalch equation, emphasizes the relationship among the PCO_2, the bicarbonate concentration, and the hydrogen ion concentration:

$$[H^+] = 24 \times PCO_2/[HCO_3^-]$$

An increase in the PCO_2 or a decrease in the bicarbonate concentration increases the hydrogen ion concentration; the pH decreases. A decrease in the PCO_2 or an increase in the bicarbonate concentration decreases the hydrogen ion concentration; the pH increases.

Terminology

Acidemia is a pH below normal (<7.35), and **alkalemia** is a pH above normal (>7.45). An acidosis is a pathologic process that causes an increase in the hydrogen ion concentration, and an alkalosis is a pathologic process that causes a decrease in the hydrogen ion concentration. Whereas acidemia is always accompanied by an acidosis, a patient can have an acidosis and a low, normal, or high pH. For example, a patient may have a mild metabolic acidosis but a simultaneous, severe respiratory alkalosis; the net result may be alkalemia. Acidemia and alkalemia indicate the pH abnormality; acidosis and alkalosis indicate the pathologic process that is taking place.

A **simple acid–base disorder** is a single primary disturbance. During a simple metabolic disorder, there is respiratory compensation. With a metabolic acidosis, the decrease in the pH increases the ventilatory drive, causing a decrease in the PCO_2. The decrease in the CO_2 concentration leads to an increase in the pH. This appropriate respiratory compensation is expected with a primary metabolic acidosis. Despite the decrease in the CO_2 concentration, appropriate respiratory compensation is not a respiratory alkalosis, even though it is sometimes erroneously called a compensatory respiratory alkalosis. A low PCO_2 can be either the result of a primary respiratory alkalosis or of an appropriate respiratory compensation for a metabolic acidosis. Appropriate respiratory compensation also occurs with a primary metabolic alkalosis, although in this case the CO_2 concentration increases to attenuate the increase in the pH. The respiratory compensation for a metabolic process happens quickly and is complete within 12-24 hr; it cannot overcompensate for or normalize the pH.

During a primary respiratory process, there is metabolic compensation, mediated by the kidneys. The kidneys respond to a respiratory acidosis by increasing hydrogen ion excretion, thereby increasing bicarbonate generation and raising the serum bicarbonate concentration. The kidneys increase bicarbonate excretion to compensate for a respiratory alkalosis; the serum bicarbonate concentration decreases. Unlike respiratory compensation, which occurs rapidly, it takes 3-4 days for the kidneys to complete appropriate metabolic compensation. There is, however, a small and rapid compensatory change in the bicarbonate concentration during a primary respiratory process. The expected appropriate metabolic compensation for a respiratory disorder depends on whether the process is acute or chronic.

A **mixed acid–base disorder** is present when there is more than 1 primary acid–base disturbance. An infant with bronchopulmonary dysplasia may have a respiratory acidosis from chronic lung disease and a metabolic alkalosis from the furosemide used to treat the chronic lung disease. More dramatically, a child with pneumonia and sepsis may have severe acidemia as a result of a combined metabolic acidosis caused by lactic acid and respiratory acidosis caused by ventilatory failure.

There are formulas for calculating the appropriate metabolic or respiratory compensation for the 6 primary simple acid–base disorders (Table 55-11). The appropriate compensation is expected in a simple disorder; it is not optional. If a patient does not have the appropriate compensation, then a mixed acid–base disorder is present. A patient has a primary metabolic acidosis with a serum bicarbonate concentration of 10 mEq/L. The expected respiratory compensation is a CO_2 concentration of 23 mm Hg ± 2 (1.5 × 10 + 8 ± 2 = 23 ± 2; Table 55-11). If the patient's CO_2 concentration is >25 mm Hg, a concurrent respiratory acidosis is present; the CO_2 concentration is higher than expected. A patient may have a respiratory acidosis despite a CO_2 level below the "normal" value of 35-45 mm Hg. In this example, a CO_2 concentration <21 mm Hg indicates a concurrent respiratory alkalosis; the CO_2 concentration is lower than expected.

Table 55-11 Appropriate Compensation During Simple Acid–Base Disorders

DISORDER	EXPECTED COMPENSATION
Metabolic acidosis	$PCO_2 = 1.5 \times [HCO_3^-] + 8 \pm 2$
Metabolic alkalosis	PCO_2 increases by 7 mm Hg for each 10 mEq/L increase in serum $[HCO_3^-]$
RESPIRATORY ACIDOSIS	
Acute	$[HCO_3^-]$ increases by 1 for each 10 mm Hg increase in PCO_2
Chronic	$[HCO_3^-]$ increases by 3.5 for each 10 mm Hg increase in PCO_2
RESPIRATORY ALKALOSIS	
Acute	$[HCO_3^-]$ falls by 2 for each 10 mm Hg decrease in PCO_2
Chronic	$[HCO_3^-]$ falls by 4 for each 10 mm Hg decrease in PCO_2

Table 55-12 Normal Values of Arterial Blood Gases

pH	7.35-7.45
$[HCO_3^-]$	20-28 mEq/L
PCO_2	35-45 mm Hg

Diagnosis

A systematic evaluation of an arterial blood gas sample, combined with the clinical history, can usually explain the patient's acid–base disturbance. Assessment of an arterial blood gas sample requires knowledge of normal values (Table 55-12). In most cases, this is accomplished via a 3-step process (Fig. 55-9):

- Determine whether acidemia or alkalemia is present.
- Determine a cause of the acidemia or alkalemia.
- Determine whether a mixed disorder is present.

Most patients with an acid–base disturbance have an abnormal pH, although there are 2 exceptions. The first exception is in the patient with a mixed disorder, wherein the 2 processes have opposite effects on pH (a metabolic acidosis and a respiratory alkalosis) and cause changes in the hydrogen ion concentration that are comparable in magnitude, albeit opposite. The second exception is in the patient with a simple chronic respiratory alkalosis; in some instances, the appropriate metabolic compensation is enough to normalize the pH. In both of these situations, the presence of an acid–base disturbance is deduced because of the abnormal CO_2 and/or bicarbonate levels. Determining the acid–base disturbance in these situations requires proceeding to the third step of this process.

The second step requires inspection of the serum bicarbonate and CO_2 concentrations to determine a cause of the abnormal pH (see Fig. 55-9). In most cases, there is only 1 obvious explanation for the abnormal pH. In some mixed disorders, however, there may be 2 possibilities (a high PCO_2 and a low $[HCO_3^-]$ in a patient with acidemia). In such cases, the patient has 2 causes for abnormal pH (a metabolic acidosis and a respiratory acidosis, in this instance), and it is unnecessary to proceed to the third step.

The third step requires determining whether the patient's compensation is appropriate. It is assumed that the primary disorder

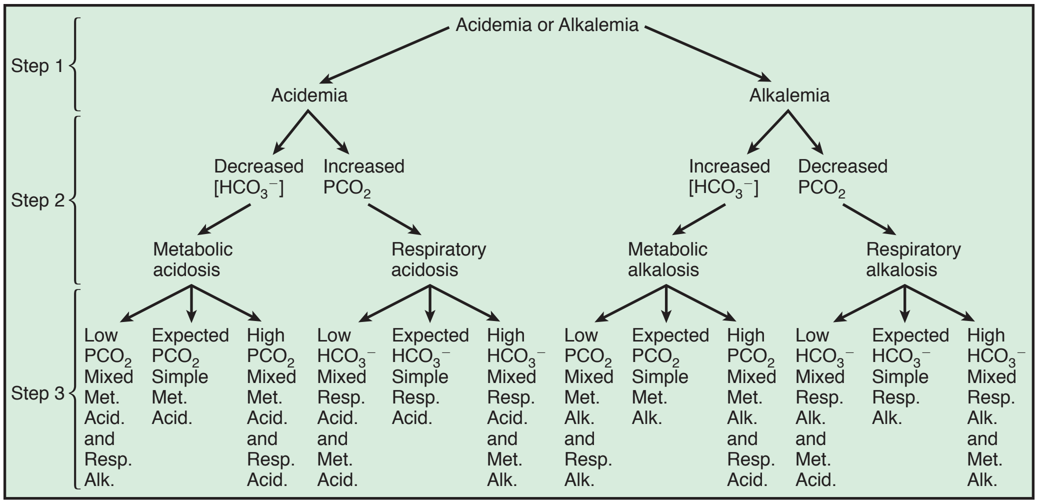

Figure 55-9 **Three-step process for interpreting acid–base disturbances.** In step 1, determine whether the pH is low (acidemia) or high (alkalemia). In step 2, establish an explanation for the acidemia or alkalemia. In step 3, calculate the expected compensation (see Table 55-11) and determine whether a mixed disturbance is present. Met. Acid., metabolic acidosis; Met. Alk., metabolic alkalosis; Resp. Acid., respiratory acidosis; Resp. Alk., respiratory alkalosis.

was diagnosed in the second step, and the expected compensation is calculated (see Table 55-11). If the compensation is appropriate, then a simple acid–base disorder is present. If the compensation is not appropriate, then a mixed disorder is present. The identity of the second disorder is determined by deciding whether the compensation is too little or too much compared with what was expected (see Fig. 55-9).

The history is always useful in evaluating and diagnosing patients with acid–base disturbances. It is especially helpful in a respiratory process. The expected metabolic compensation for a respiratory process changes according to whether the process is acute or chronic, which can be deduced only from the history. The metabolic compensation for an acute respiratory acidosis is less than that for a chronic respiratory acidosis. In a patient with a respiratory acidosis, a small increase in the bicarbonate concentration would be consistent with a simple acute respiratory acidosis or a mixed disorder (a chronic respiratory acidosis and a metabolic acidosis). Only the history can differentiate among the possibilities. Knowledge of the length of the respiratory process and the presence or absence of a risk factor for a metabolic acidosis (diarrhea) allows the correct conclusion to be reached.

METABOLIC ACIDOSIS

Metabolic acidosis occurs frequently in hospitalized children; diarrhea is the most common etiology. For a patient with an unknown medical problem, the presence of a metabolic acidosis is often helpful diagnostically, because it suggests a relatively narrow differential diagnosis.

Patients with a metabolic acidosis have a low serum bicarbonate concentration, although not every patient with a low serum bicarbonate concentration has a metabolic acidosis. The exception is the patient with a respiratory alkalosis, which causes a decrease in the serum bicarbonate concentration as part of appropriate renal compensation. In a patient with an isolated metabolic acidosis, there is a predictable decrease in the blood CO_2 concentration, as follows:

$$P_{CO_2} = 1.5 \times [HCO_3^-] + 8 \pm 2$$

A mixed acid–base disturbance is present if the respiratory compensation is not appropriate. If the P_{CO_2} is greater than predicted, then the patient has a concurrent respiratory acidosis. A lower P_{CO_2} than predicted indicates a concurrent respiratory alkalosis or, less commonly, an isolated respiratory alkalosis. Because the appropriate respiratory compensation for a metabolic acidosis **never normalizes** the patient's pH, the presence of a normal pH and a low bicarbonate concentration occurs only if some degree of respiratory alkalosis is present. In this situation, distinguishing an isolated chronic respiratory alkalosis from a mixed metabolic acidosis and acute respiratory alkalosis may be possible only clinically. In contrast, the combination of a low serum pH and a low bicarbonate concentration occurs only if a metabolic acidosis is present.

Etiology and Pathophysiology

There are many causes of a metabolic acidosis (Table 55-13), which occur via 3 basic mechanisms:

- Loss of bicarbonate from the body
- Impaired ability to excrete acid by the kidney
- Addition of acid to the body (exogenous or endogenous)

Diarrhea, the most common cause of metabolic acidosis in children, causes a loss of bicarbonate from the body. The amount of bicarbonate lost in the stool depends on the volume of diarrhea and the bicarbonate concentration of the stool, which tends to increase with more severe diarrhea. The kidneys attempt to balance the losses by increasing acid secretion, but metabolic acidosis occurs when this compensation is inadequate. Diarrhea often causes volume depletion as a result of losses of sodium and water, potentially exacerbating the acidosis by causing shock and a lactic acidosis. In addition, diarrheal losses of potassium lead to hypokalemia. Moreover, the volume depletion causes increased production of aldosterone. This increase stimulates renal retention of sodium, helping to maintain intravascular volume, but also leads to increased urinary losses of potassium, exacerbating the hypokalemia.

There are 3 forms of RTA: distal (type I), proximal (type II), and hyperkalemic (type IV) (see Chapter 529). In distal RTA, children may have accompanying hypokalemia, hypercalciuria, nephrolithiasis, and nephrocalcinosis. Failure to thrive because of chronic metabolic acidosis is the most common presenting complaint. Patients with distal RTA cannot acidify their urine and, thus, have a urine pH >5.5 despite a metabolic acidosis.

Proximal RTA is rarely present in isolation. In most patients, proximal RTA is part of Fanconi syndrome, a generalized dysfunction of the proximal tubule. The dysfunction leads to glycosuria, aminoaciduria, and excessive urinary losses of phosphate and uric acid. The presence of a low serum uric acid level, glycosuria, and aminoaciduria is helpful diagnostically. Chronic hypophosphatemia leads to rickets in children (see Chapter 51). Rickets and/or failure to thrive may be the presenting complaint. The ability to acidify the urine is intact in proximal RTA; thus, untreated patients have a urine pH <5.5. However, bicarbonate therapy increases bicarbonate losses in the urine, and the urine pH increases.

In hyperkalemic RTA, renal excretion of acid and potassium is impaired. Hyperkalemic RTA is the result of either an absence of

*Along with these genetic disorders, distal RTA may be secondary to renal disease or medications.
†Most cases of proximal RTA are not caused by this primary genetic disorder. Proximal RTA is usually part of Fanconi syndrome, which has multiple etiologies.
‡Hyperkalemic RTA can be secondary to a genetic disorder (some of the more common are listed) or other etiologies.
OMIM, database number from the Online Mendelian Inheritance in Man (http://www.ncbi.nlm.nih.gov/omim).

aldosterone or an inability of the kidney to respond to aldosterone. In severe aldosterone deficiency, as occurs with congenital adrenal hyperplasia because of 21α-hydroxylase deficiency, the hyperkalemia and metabolic acidosis are accompanied by hyponatremia and volume depletion from renal salt wasting. Incomplete aldosterone deficiency causes less-severe electrolyte disturbances; children may have isolated hyperkalemic RTA, hyperkalemia without acidosis, or isolated hyponatremia. Patients may have aldosterone deficiency caused by decreased renin production by the kidney; renin normally stimulates aldosterone synthesis. Children with hyporeninemic hypoaldosteronism usually have either isolated hyperkalemia or hyperkalemic RTA. The manifestations of aldosterone resistance depend on the severity of the resistance. In the autosomal recessive form of pseudohypoaldosteronism type I, which is the result of an absence of the sodium channel that normally responds to aldosterone, there is often severe salt wasting and hyponatremia. In contrast, the aldosterone resistance in kidney transplant recipients usually produces either isolated hyperkalemia or hyperkalemic RTA; hyponatremia is unusual. Similarly, the medications that cause hyperkalemic RTA do not cause hyponatremia. Pseudohypoaldosteronism type II, an autosomal recessive disorder also known as **Gordon syndrome,** is a unique cause of hyperkalemic RTA because the genetic defect causes volume expansion and hypertension.

Children with **abnormal urinary tracts,** usually secondary to congenital malformations, may require diversion of urine through intestinal segments. Ureterosigmoidostomy, anastomosis of a ureter to the sigmoid colon, almost always produces a metabolic acidosis and hypokalemia. Consequently, ileal conduits are now the more commonly used procedure, although there is still a risk of a metabolic acidosis.

The **appropriate metabolic compensation for a chronic respiratory alkalosis** is a decrease in renal acid excretion. The resultant decrease in the serum bicarbonate concentration lessens the alkalemia caused by the respiratory alkalosis. If the respiratory alkalosis resolves quickly, the patient continues to have a decreased serum bicarbonate concentration, causing acidemia as the result of a metabolic acidosis. This resolves over 1-2 days via increased acid excretion by the kidneys.

Lactic acidosis most commonly occurs when inadequate oxygen delivery to the tissues leads to anaerobic metabolism and excess production of lactic acid. Lactic acidosis may be secondary to shock, severe anemia, or hypoxemia. When the underlying cause of the lactic acidosis is alleviated, the liver is able to metabolize the accumulated lactate into bicarbonate, correcting the metabolic acidosis. There is normally some tissue production of lactate that is metabolized by the liver. In children with severe liver dysfunction, impairment of lactate metabolism may produce a lactic acidosis. Rarely, a metabolically active malignancy grows so fast that its blood supply becomes inadequate, with resultant anaerobic metabolism and lactic acidosis. Patients who have short bowel syndrome resulting from small bowel resection can have bacterial overgrowth. In these patients, excessive bacterial metabolism of glucose into D-lactic acid can cause a lactic acidosis. Lactic acidosis occurs in a variety of inborn errors of metabolism, especially those affecting mitochondrial oxidation (see Chapter 87.4). Finally, medications can cause lactic acidosis. Nucleoside reverse transcriptase inhibitors that are used to treat HIV infection inhibit mitochondrial replication; lactic acidosis is a rare complication, although elevated serum lactate concentrations without acidosis are quite common. Metformin, commonly used for treating type 2 diabetes mellitus, is most likely to cause a lactic acidosis in patients with renal insufficiency. High dosages and prolonged use of propofol can cause lactic acidosis. Propylene glycol is a diluent in a variety of oral and intravenous medications; excessive intake causes a lactic acidosis, principally from accumulation of D-lactic acid.

In **insulin-dependent diabetes mellitus,** inadequate insulin leads to hyperglycemia and diabetic ketoacidosis (see Chapter 589). Production of acetoacetic acid and β-hydroxybutyric acid causes the metabolic acidosis. Administration of insulin corrects the underlying metabolic problem and permits conversion of acetoacetate and β-hydroxybutyrate into bicarbonate, which helps correct the metabolic acidosis. However, in some patients, urinary losses of acetoacetate and β-hydroxybutyrate may be substantial, preventing rapid regeneration of bicarbonate. In these patients, full correction of the metabolic acidosis requires renal regeneration of bicarbonate, a slower process. The hyperglycemia causes an osmotic diuresis, usually producing volume depletion, along with substantial losses of potassium, sodium, and phosphate.

In **starvation ketoacidosis,** the lack of glucose leads to keto acid production, which, in turn, can produce a metabolic acidosis, although it is usually mild as a result of increased acid secretion by the kidney. In alcoholic ketoacidosis, which is much less common in children than in adults, the acidosis usually follows a combination of an alcoholic binge with vomiting and poor intake of food. The acidosis is potentially more severe than with isolated starvation, and the blood glucose level may be low, normal, or high. Hypoglycemia and acidosis also suggest an inborn error of metabolism.

Renal failure causes a metabolic acidosis because of the need for the kidneys to excrete the acid produced by normal metabolism. With mild or moderate renal insufficiency, the remaining nephrons are usually able to compensate by increasing acid excretion. When the GFR is <20-30% of normal, the compensation is inadequate and a metabolic acidosis develops. In some children, especially those with chronic renal failure because of tubular damage, the acidosis develops at a higher GFR because of a concurrent defect in acid secretion by the distal tubule (distal RTA).

A variety of **toxic ingestions** (see Chapter 63) can cause a metabolic acidosis. **Salicylate** intoxication is now much less common because aspirin is no longer recommended for fever control in children. Acute

salicylate intoxication occurs after a large overdose. Chronic salicylate intoxication is possible with gradual buildup of the drug. Especially in adults, respiratory alkalosis may be the dominant acid–base disturbance. In children, the metabolic acidosis is usually the more significant finding. Other symptoms of salicylate intoxication are fever, seizures, lethargy, and coma. Hyperventilation may be particularly marked. Tinnitus, vertigo, and hearing impairment are more likely with chronic salicylate intoxication.

Ethylene glycol, a component of antifreeze, is converted in the liver to glyoxylic and oxalic acids, causing a severe metabolic acidosis. Excessive oxalate excretion causes calcium oxalate crystals to appear in the urine, and calcium oxalate precipitation in the kidney tubules can cause renal failure. The toxicity of methanol ingestion also depends on liver metabolism; formic acid is the toxic end product that causes the metabolic acidosis and other sequelae, which include damage to the optic nerve and CNS. Symptoms may include nausea, emesis, visual impairment, and altered mental status. Toluene inhalation and paraldehyde ingestion are other potential causes of a metabolic acidosis.

Many **inborn errors of metabolism** cause a metabolic acidosis (see Chapters 84-87). The metabolic acidosis may be the result of excessive production of keto acids, lactic acid, and/or other organic anions. Some patients have accompanying hypoglycemia or hyperammonemia. In most patients, the acidosis occurs episodically, only during acute decompensations, which may be precipitated by ingestion of specific dietary substrates, the stress of a mild illness, or poor compliance with dietary or medical therapy. In a few inborn errors of metabolism, patients have a chronic metabolic acidosis.

Clinical Manifestations

The underlying disorder usually produces most of the signs and symptoms in children with a mild or moderate metabolic acidosis. The clinical manifestations of the acidosis are related to the degree of acidemia; patients with appropriate respiratory compensation and less severe acidemia have fewer manifestations than those with a concomitant respiratory acidosis. At a serum pH <7.2, there may be impaired cardiac contractility and an increased risk of arrhythmias, especially if underlying heart disease or other predisposing electrolyte disorders are present. With acidemia, there may be a decrease in the cardiovascular response to catecholamines, potentially exacerbating hypotension in children with volume depletion or shock. Acidemia causes vasoconstriction of the pulmonary vasculature, which is especially problematic in newborn infants with persistent pulmonary hypertension (see Chapter 101.7).

The normal respiratory response to metabolic acidosis—compensatory hyperventilation—may be subtle with mild metabolic acidosis, but it causes discernible increased respiratory effort with worsening acidemia. The acute metabolic effects of acidemia include insulin resistance, increased protein degradation, and reduced ATP synthesis. Chronic metabolic acidosis causes failure to thrive in children. Acidemia causes potassium to move from the intracellular space to the extracellular space, thereby increasing the serum potassium concentration. Severe acidemia impairs brain metabolism, eventually resulting in lethargy and coma.

Diagnosis

The etiology of a metabolic acidosis is often apparent from the history and physical examination. Acutely, diarrhea and shock are common causes of a metabolic acidosis. Shock, which causes a lactic acidosis, is usually apparent on physical examination and can be secondary to dehydration, acute blood loss, sepsis, or heart disease. Failure to thrive suggests a chronic metabolic acidosis, as happens with renal insufficiency or RTA. New onset of polyuria occurs in children with undiagnosed diabetes mellitus and diabetic ketoacidosis. Metabolic acidosis with seizures and/or a depressed sensorium, especially in an infant, warrants consideration of an inborn error of metabolism. Meningitis and sepsis with lactic acidosis are more common explanations for metabolic acidosis with neurologic signs and symptoms. Identification of a toxic ingestion such as of ethylene glycol or methanol is especially important because of the potentially excellent response to specific therapy. A variety of medications can cause a metabolic acidosis; they may be prescribed or accidentally ingested. Hepatomegaly and metabolic acidosis may occur in children with sepsis, congenital or acquired heart disease, hepatic failure, or inborn errors of metabolism.

Basic laboratory tests in a child with a metabolic acidosis should include measurements of BUN, serum creatinine, serum glucose, urinalysis, and serum electrolytes. Elevated BUN and creatinine values are present in renal insufficiency, whereas an elevated BUN : creatinine ratio (>20 : 1) supports a diagnosis of prerenal azotemia and the possibility of poor perfusion with lactic acidosis. Metabolic acidosis, hyperglycemia, glycosuria, and ketonuria support a diagnosis of diabetic ketoacidosis. Starvation causes ketosis, but the metabolic acidosis, if present, is usually mild (HCO_3^- >18). In most children with ketosis from poor intake and metabolic acidosis there is a concomitant disorder, such as gastroenteritis with diarrhea, that explains the metabolic acidosis. Alternatively, metabolic acidosis with or without ketosis occurs in inborn errors of metabolism; patients with these disorders may have hyperglycemia, normoglycemia, or hypoglycemia. Adrenal insufficiency may cause metabolic acidosis and hypoglycemia. Metabolic acidosis with hypoglycemia also occurs with liver failure. Metabolic acidosis, normoglycemia, and glycosuria occur in children when type II RTA is part of Fanconi syndrome; the defect in resorption of glucose by the proximal tubule of the kidney causes the glycosuria.

The serum potassium level is often abnormal in children with a metabolic acidosis. Even though a metabolic acidosis causes potassium to move from the intracellular space to the extracellular space, many patients with a metabolic acidosis have a low serum potassium level owing to excessive body losses of potassium. With diarrhea, there are high stool losses of potassium and often secondary renal losses of potassium, whereas in type I or type II RTA, there are increased urinary losses of potassium. In diabetic ketoacidosis, urinary losses of potassium are high, but the shift of potassium out of cells because of a lack of insulin and metabolic acidosis is especially significant. Consequently, the initial serum potassium level can be low, normal, or high, even though total body potassium is almost always decreased. The serum potassium level is usually increased in patients with acidosis due to renal insufficiency; urinary potassium excretion is impaired. The combination of metabolic acidosis, hyperkalemia, and hyponatremia occurs in patients with severe aldosterone deficiency (adrenogenital syndrome) or aldosterone resistance. Patients with less severe, type IV RTA often have only hyperkalemia and metabolic acidosis. Very ill children with metabolic acidosis may have an elevated serum potassium value as a result of a combination of renal insufficiency, tissue breakdown, and a shift of potassium from the intracellular space to the extracellular space secondary to the metabolic acidosis.

The **plasma anion gap** is useful for evaluating patients with a metabolic acidosis. It divides patients into 2 diagnostic groups, those with normal anion gap and those with increased anion gap. The following formula determines the anion gap:

$$\text{Anion gap} = [Na^+] - [Cl^-] - [HCO_3^-]$$

A normal anion gap is 4-11, although there is variation among laboratories. The number of serum anions must equal the number of serum cations to maintain electrical neutrality (Fig. 55-10). The anion gap is the difference between the measured cation (sodium) and the measured anions (chloride + bicarbonate). The anion gap is also the difference between the unmeasured cations (potassium, magnesium, calcium) and the unmeasured anions (albumin, phosphate, urate, sulfate). An increased anion gap occurs when there is an increase in unmeasured anions. With a lactic acidosis, there is endogenous production of lactic acid, which is composed of positively charged hydrogen ions and negatively charged lactate anions. The hydrogen ions are largely buffered by serum bicarbonate, resulting in a decrease in the bicarbonate concentration. The hydrogen ions that are not buffered by bicarbonate cause the serum pH to decrease. The lactate anions remain, causing the increase in the anion gap.

An increase in unmeasured anions, along with hydrogen ion generation, is present in all causes of an increased gap metabolic acidosis (see Table 55-13). In diabetic ketoacidosis, the keto acids β-hydroxybutyrate

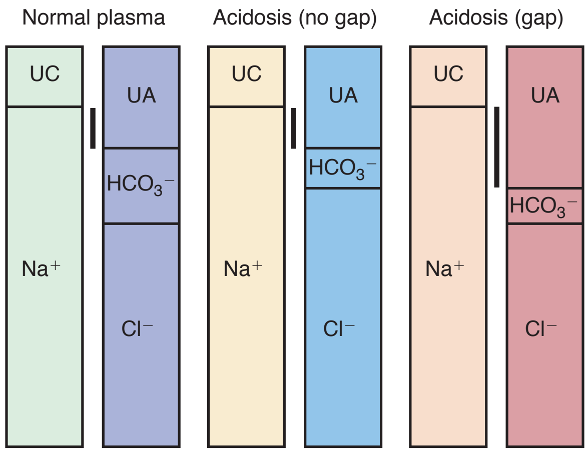

Figure 55-10 The anion gap, which is the difference between the sodium concentration and the combined concentrations of chloride and bicarbonate *(vertical lines)*. In both a gap and a nongap metabolic acidosis, there is a decrease in the bicarbonate concentration. There is an increase in unmeasured anions (UA) in patients with a gap metabolic acidosis. In a nongap metabolic acidosis, there is an increase in the serum chloride concentration. UC, unmeasured cations.

and acetoacetate are the unmeasured anions. In renal failure, there is retention of unmeasured anions, including phosphate, urate, and sulfate. The increase in unmeasured anions in renal failure is usually less than the decrease in the bicarbonate concentration. Renal failure is thus a mix of an increased gap and a normal gap metabolic acidosis. The normal gap metabolic acidosis is especially prominent in children with renal failure as a result of tubular damage, as occurs with renal dysplasia or obstructive uropathy, because these patients have a concurrent RTA. The unmeasured anions in toxic ingestions vary: formate in methanol intoxication, glycolate in ethylene glycol intoxication, and lactate and keto acids in salicylate intoxication. In inborn errors of metabolism, the unmeasured anions depend on the specific etiology and may include keto acids, lactate, and other organic anions. In a few inborn errors of metabolism, the acidosis occurs without generation of unmeasured anions; thus, the anion gap is normal.

A **normal anion gap** metabolic acidosis occurs when there is a decrease in the bicarbonate concentration without an increase in the unmeasured anions. With diarrhea, there is a loss of bicarbonate in the stool, causing a decrease in the serum pH and bicarbonate concentration; the serum chloride concentration increases to maintain electrical neutrality (see Fig. 55-10). Hyperchloremic metabolic acidosis is an alternative term for a normal anion gap metabolic acidosis. Calculation of the anion gap is more precise than using the chloride concentration to differentiate between a normal and an increased gap metabolic acidosis, in that the anion gap directly determines the presence of unmeasured anions. Electrical neutrality dictates that the chloride concentration increases or decreases according to the serum sodium concentration, making the chloride concentration a less reliable predictor of unmeasured anions than the more direct measure, calculation of the anion gap.

Approximately 11 mEq of the anion gap is normally secondary to albumin. A 1 g/dL decrease in the albumin concentration decreases the anion gap by roughly 2.5 mEq/L. Similarly, an increase in unmeasured cations, such as calcium, potassium, and magnesium, decreases the anion gap. Conversely, a decrease in unmeasured cations is a very unusual cause of an increased anion gap. Because of these variables, the broad range of a normal anion gap, and other variables, the presence of a normal or an increased anion gap is not always reliable in differentiating among the causes of a metabolic acidosis, especially when the metabolic acidosis is mild. In some patients there is more than 1 explanation for the metabolic acidosis, such as the child with diarrhea and lactic acidosis as a result of poor perfusion. The anion gap should not be interpreted in dogmatic isolation; consideration of other laboratory abnormalities and the clinical history improves its diagnostic utility.

Treatment

The most effective therapeutic approach for patients with a metabolic acidosis is repair of the underlying disorder, if possible. The administration of insulin in diabetic ketoacidosis and the restoration of adequate perfusion with intravenous fluids in lactic acidosis because of hypovolemia or shock eventually result in normalization of the acid–base balance. In other diseases, the use of bicarbonate therapy is indicated because the underlying disorder is irreparable. Children with metabolic acidosis caused by RTA or chronic renal failure require long-term base therapy. Patients with acute renal failure and metabolic acidosis need base therapy until their kidneys' ability to excrete hydrogen normalizes. In other disorders, the cause of the metabolic acidosis eventually resolves, but base therapy is necessary during the acute illness. In salicylate poisoning, alkali administration increases renal clearance of salicylate and decreases the amount of salicylate in brain cells. Short-term base therapy is often necessary in other poisonings (ethylene glycol, methanol) and inborn errors of metabolism (pyruvate carboxylase deficiency, propionic acidemia). Some inborn errors of metabolism require long-term base therapy.

The use of base therapy in diabetic ketoacidosis and lactic acidosis is controversial; there is little evidence that it improves patient outcome, and it has a variety of potential side effects. The risks of giving sodium bicarbonate include the possibility of causing hypernatremia or volume overload. Furthermore, the patient may have overcorrection of the metabolic acidosis once the underlying disorder resolves, because metabolism of lactate or keto acids generates bicarbonate. The rapid change from acidemia to alkalemia can cause a variety of problems, including hypokalemia and hypophosphatemia. Bicarbonate therapy increases the generation of CO_2, which can accumulate in patients with respiratory failure. Because CO_2 readily diffuses into cells, the administration of bicarbonate can lower the intracellular pH, potentially worsening cell function. Base therapy is usually reserved for children with severe acute lactic acidosis and severe diabetic ketoacidosis.

Oral base therapy is given to children with chronic metabolic acidosis. Sodium bicarbonate tablets are available for older children. Younger children generally take citrate solutions; the liver generates bicarbonate from citrate. Citrate solutions are available as sodium citrate, potassium citrate, and a 1 : 1 mix of sodium citrate and potassium citrate. The patient's potassium needs dictate the choice. Children with type I or type II RTA may have hypokalemia and may benefit from potassium supplements, whereas most children with chronic renal failure cannot tolerate additional potassium.

Oral or intravenous base can be used in acute metabolic acidosis; intravenous therapy is generally used when a rapid response is necessary. Sodium bicarbonate may be given as a bolus, usually at a dose of 1 mEq/kg, in an emergency situation. Another approach is to add sodium bicarbonate or sodium acetate to the patient's intravenous fluids, remembering to remove an equal amount of sodium chloride from the solution to avoid giving an excessive sodium load. Careful monitoring is mandatory so that the dose of base can be titrated appropriately. Tris-hydroxymethyl aminomethane (THAM) is an option in patients with a metabolic acidosis and a respiratory acidosis, because it neutralizes acids without releasing CO_2. THAM also diffuses into cells and therefore provides intracellular buffering.

Hemodialysis is another option for correcting a metabolic acidosis, and it is an appropriate choice in patients with renal insufficiency, especially if significant uremia or hyperkalemia is also present. Hemodialysis is advantageous for correcting the metabolic acidosis caused by methanol or ethylene glycol intoxication, because hemodialysis removes the offending toxin. In addition, these patients often have a severe metabolic acidosis that does not respond easily to intravenous bicarbonate therapy. Peritoneal dialysis is another option for correcting the metabolic acidosis due to renal insufficiency, although, because it relies on lactate as the source of base, it may not correct the metabolic acidosis in patients with concomitant renal failure and lactic acidosis.

Many causes of metabolic acidosis require specific therapy. Administration of a glucocorticoid and a mineralocorticoid is necessary in patients with adrenal insufficiency. Patients with diabetic ketoacidosis require insulin therapy, whereas patients with lactic acidosis respond to measures that alleviate tissue hypoxia. Along with correction of acidosis, patients with methanol or ethylene glycol ingestion should receive an agent that prevents the breakdown of the toxic substance to its toxic metabolites. Fomepizole has supplanted ethanol as the treatment of choice. These agents work by inhibiting alcohol dehydrogenase, the enzyme that performs the first step in the metabolism of ethylene glycol or methanol. There are a variety of disease-specific therapies for patients with a metabolic acidosis resulting from an inborn error of metabolism.

METABOLIC ALKALOSIS

Metabolic alkalosis in children is most commonly secondary to emesis or diuretic use. The serum bicarbonate concentration is increased with a metabolic alkalosis, although a respiratory acidosis also leads to a compensatory elevation of the serum bicarbonate concentration. With a simple metabolic alkalosis, however, the pH is elevated; alkalemia is present. Patients with a respiratory acidosis are acidemic. A metabolic alkalosis, by decreasing ventilation, causes appropriate respiratory compensation. P_{CO_2} increases by 7 mm Hg for each 10 mEq/L increase in the serum bicarbonate concentration. Appropriate respiratory compensation never exceeds a P_{CO_2} of 55-60 mm Hg. The patient has a concurrent respiratory alkalosis if the P_{CO_2} is lower than the expected compensation. A greater-than-expected P_{CO_2} occurs with a concurrent respiratory acidosis.

Table 55-14 Causes of Metabolic Alkalosis

Etiology and Pathophysiology

The kidneys normally respond promptly to a metabolic alkalosis by increasing base excretion. Two processes are therefore usually present to produce a metabolic alkalosis. The first process is the generation of the metabolic alkalosis, which requires the addition of base to the body. The second process is the maintenance of the metabolic alkalosis, which requires impairment in the kidney's ability to excrete base.

The etiologies of a metabolic alkalosis are divided into 2 categories on the basis of urinary chloride level (Table 55-14). The alkalosis in patients with a **low urinary chloride** level is maintained by **volume depletion;** thus, volume repletion is necessary for correction of the alkalosis. The volume depletion in these patients is caused by losses of sodium and potassium, but the loss of chloride is usually greater than the losses of sodium and potassium combined. Because chloride losses are the dominant cause of the volume depletion, these patients require chloride to correct the volume depletion and metabolic alkalosis; they are said to have **chloride-responsive metabolic alkalosis.** In contrast, the alkalosis in a patient with an elevated urinary chloride concentration does not respond to volume repletion and so is termed **chloride-resistant metabolic alkalosis.**

Emesis or nasogastric suction results in **loss of gastric fluid,** which has a high content of HCl. Generation of hydrogen ions by the gastric mucosa causes simultaneous release of bicarbonate into the bloodstream. Normally, the hydrogen ions in gastric fluid are reclaimed in the small intestine (by neutralizing secreted bicarbonate). Thus, there is no net loss of acid. With loss of gastric fluid, this does not occur, and a metabolic alkalosis develops. This period is the generation phase of the metabolic alkalosis.

The maintenance phase of the metabolic alkalosis from gastric losses is due to the volume depletion ("chloride depletion" from gastric loss of HCl). Volume depletion interferes with urinary loss of bicarbonate, the normal renal response to a metabolic alkalosis. During volume depletion, several mechanisms prevent renal bicarbonate loss. First, there is a reduction in the GFR, so less bicarbonate is filtered. Second, volume depletion increases resorption of sodium and bicarbonate in the proximal tubule, limiting the amount of bicarbonate that can be excreted in the urine. This effect is mediated by angiotensin II and by adrenergic stimulation of the kidney, which are both increased in response to volume depletion. Third, the increase in aldosterone during volume depletion increases bicarbonate resorption and hydrogen ion secretion in the collecting duct.

In addition to volume depletion, gastric losses are usually associated with hypokalemia as a result of both gastric loss of potassium and, most importantly, increased urinary potassium losses. The increased urinary losses of potassium are mediated by aldosterone, through volume depletion, and by the increase in intracellular potassium secondary to the metabolic alkalosis, which causes potassium to move into the cells of the kidney, causing increased potassium excretion. Hypokalemia contributes to the maintenance of the metabolic alkalosis by decreasing bicarbonate loss. Hypokalemia increases hydrogen ion secretion in the distal nephron and stimulates ammonia production in the proximal tubule. Ammonia production enhances renal excretion of hydrogen ions.

A metabolic alkalosis can develop in patients receiving **loop** or **thiazide diuretics.** Diuretic use leads to volume depletion, which increases angiotensin II, aldosterone, and adrenergic stimulation of the kidney. Diuretics increase the delivery of sodium to the distal nephron, further enhancing acid excretion. Moreover, these diuretics cause hypokalemia, which increases acid excretion by the kidney. The increase in renal acid excretion generates the metabolic alkalosis, and the decrease in bicarbonate loss maintains it. In addition, patients who are receiving diuretics have a "contraction alkalosis." Diuretic use causes fluid loss without bicarbonate; thus, the remaining body bicarbonate is contained in a smaller total body fluid compartment. The bicarbonate concentration increases, helping to generate the metabolic alkalosis.

Diuretics are often used in patients with edema, such as those with nephrotic syndrome, heart failure, or liver failure. In many of these patients, metabolic alkalosis resulting from diuretic use develops despite the continued presence of edema. This is because the effective intravascular volume is low, and it is the effective intravascular volume that stimulates the compensatory mechanisms that cause and maintain a metabolic alkalosis. Many of these patients have a decreased effective intravascular volume before they begin diuretic therapy, increasing the likelihood of diuretic-induced metabolic alkalosis.

Diuretic use increases chloride excretion in the urine. Consequently, while a patient is receiving diuretics, the urine chloride level is typically

high (>20 mEq/L). After the diuretic effect has worn off, the urinary chloride level is low (<15 mEq/L) owing to appropriate renal chloride retention in response to volume depletion. Thus, categorization of diuretics on the basis of urinary chloride level depends on the timing of the measurement. However, the metabolic alkalosis from diuretics is clearly chloride responsive; it is corrected after adequate volume repletion. This is the rationale for including this process among the chloride-responsive causes of a metabolic alkalosis.

Most patients with diarrhea have a metabolic acidosis as a result of stool losses of bicarbonate. In **chloride-losing diarrhea,** an autosomal recessive disorder, there is a defect in the normal intestinal exchange of bicarbonate for chloride, causing excessive stool losses of chloride (see Chapter 338). In addition, stool losses of hydrogen ions and potassium cause metabolic alkalosis and hypokalemia, both of which are exacerbated by increased renal hydrogen and potassium losses from volume depletion. Treatment is with oral supplements of potassium and sodium chloride. Use of a gastric proton pump inhibitor, by decreasing gastric HCl production, reduces both the volume of diarrhea and the need for electrolyte supplementation.

An infant formula with extremely low chloride content has led to chloride deficiency and volume depletion. The infants fed this formula, which is no longer available, had a metabolic alkalosis and hypokalemia. **Cystic fibrosis** can rarely cause metabolic alkalosis, hypokalemia, and hyponatremia because of excessive losses of sodium chloride in sweat (see Chapter 403). The volume depletion causes the metabolic alkalosis and hypokalemia through increased urinary losses, whereas the hyponatremia, a less-common finding, is secondary to sodium loss combined with renal water conservation in an effort to protect the intravascular volume ("appropriate" ADH production).

A **posthypercapnic metabolic alkalosis** occurs after the correction of a chronic respiratory acidosis. This is typically seen in patients with chronic lung disease who are started on mechanical ventilation. During chronic respiratory acidosis, appropriate renal compensation leads to an increase in the serum bicarbonate concentration. This elevated bicarbonate concentration, because it is still present after acute correction of the respiratory acidosis, causes a metabolic alkalosis. The metabolic alkalosis persists because the patient with a chronic respiratory acidosis is intravascularly depleted because of the chloride loss that occurred during the initial metabolic compensation for the primary respiratory acidosis. In addition, many children with a chronic respiratory acidosis receive diuretics, which further decrease the intravascular volume. The metabolic alkalosis responds to correction of the intravascular volume deficit.

The **chloride-resistant** causes of metabolic alkalosis can be subdivided according to blood pressure status. Patients with **hypertension** either have increased aldosterone levels or act as if they do. Aldosterone levels are elevated in children with adrenal adenomas or hyperplasia. Aldosterone causes renal retention of sodium, with resultant hypertension. Metabolic alkalosis and hypokalemia result from aldosterone-mediated renal excretion of hydrogen ions and potassium. The urinary chloride level is not low because these patients are volume-overloaded, not volume-depleted. The volume expansion and hypertension allow normal excretion of sodium and chloride despite the presence of aldosterone. This is known as the mineralocorticoid escape phenomenon.

In **glucocorticoid-remediable aldosteronism,** an autosomal dominant disorder, there is excess production of aldosterone owing to the presence of an aldosterone synthase gene that is regulated by adrenocorticotropic hormone (ACTH) (see Chapter 576.8). Glucocorticoids effectively treat this disorder by inhibiting ACTH production by the pituitary, downregulating the inappropriate aldosterone production. Renovascular disease and renin-secreting tumors both cause excessive renin, leading to an increase in aldosterone, although hypokalemia and metabolic alkalosis are less-common findings than hypertension. In 2 forms of **congenital adrenal hyperplasia,** 11β-hydroxylase deficiency and 17α-hydroxylase deficiency, there is excessive production of the mineralocorticoid 11-deoxycorticosterone (see Chapters 576.2 and 576.4). Hypertension, hypokalemia, and metabolic alkalosis are more likely in 17α-hydroxylase deficiency than in 11β-hydroxylase deficiency. These disorders respond to glucocorticoids because the excess production of 11-deoxycorticosterone is under the control of ACTH.

Cushing syndrome frequently causes hypertension. Cortisol has some mineralocorticoid activity, and high levels can produce hypokalemia and metabolic alkalosis in patients with Cushing syndrome.

Cortisol can bind to the mineralocorticoid receptors in the kidney and function as a mineralocorticoid. This binding normally does not occur because 11β-hydroxysteroid dehydrogenase in the kidney converts cortisol to cortisone, which does not bind to the mineralocorticoid receptor. In 11β-hydroxysteroid dehydrogenase deficiency, also called **apparent mineralocorticoid excess,** cortisol is not converted in the kidney to cortisone. Cortisol is therefore available to bind to the mineralocorticoid receptor in the kidney and act as a mineralocorticoid. Patients with this deficiency, despite low levels of aldosterone, are hypertensive and hypokalemic, and they have a metabolic alkalosis. The same phenomenon can occur with excessive intake of natural licorice, a component of which, glycyrrhizic acid, inhibits 11β-hydroxysteroid dehydrogenase. The autosomal dominant disorder **Liddle syndrome** is secondary to an activating mutation of the sodium channel in the distal nephron (see Chapter 531.3). Upregulation of this sodium channel is one of the principal actions of aldosterone. Because this sodium channel is continuously open, children with Liddle syndrome have the features of hyperaldosteronism, including hypertension, hypokalemia, and metabolic alkalosis, but low serum levels of aldosterone.

Bartter syndrome and **Gitelman syndrome** are autosomal recessive disorders associated with **normal blood pressure,** elevations of urinary chloride, metabolic alkalosis, and hypokalemia (see Chapter 531). In Bartter syndrome, patients have a defect in sodium and chloride resorption in the loop of Henle. This leads to excessive urinary losses of sodium and chloride, and as in patients receiving loop diuretics, volume depletion and secondary hyperaldosteronism occur, causing hypokalemia and metabolic alkalosis. Gitelman syndrome is usually milder than Bartter syndrome. Patients have renal sodium and chloride wasting with volume depletion due mutations in the gene encoding the thiazide-sensitive sodium-chloride transporter in the distal tubule. As in patients receiving a thiazide diuretic, affected patients have volume depletion and secondary hyperaldosteronism with hypokalemia and metabolic alkalosis. Children with Gitelman syndrome have hypocalciuria and hypomagnesemia. Some patients with autosomal dominant hypoparathyroidism have hypokalemia and metabolic alkalosis due to impaired sodium and chloride resorption in the loop of Henle. **EAST syndrome** causes hypokalemia, metabolic alkalosis and hypomagnesemia.

Excessive base intake can cause a metabolic alkalosis. Affected patients do not have a low urine chloride level, unless there is associated volume depletion. In the absence of volume depletion, excess base is rapidly corrected via renal excretion of bicarbonate. Rarely, massive base intake can cause a metabolic alkalosis by overwhelming the kidney's ability to excrete bicarbonate. This may occur in infants who are given baking soda as a "home remedy" for colic or stomach upset. Each teaspoon of baking soda has 42 mEq of sodium bicarbonate. Infants have increased vulnerability because of a lower GFR, limiting the rate of compensatory renal bicarbonate excretion. A metabolic alkalosis may also occur in patients who receive a large amount of sodium bicarbonate during cardiopulmonary resuscitation. Blood products are anticoagulated with citrate, which is converted into bicarbonate by the liver. Patients who receive large amounts of blood products may have a metabolic alkalosis. Iatrogenic metabolic alkalosis can occur as a result of acetate in total parenteral nutrition. Aggressive use of bicarbonate therapy in a child with a lactic acidosis or diabetic ketoacidosis may cause a metabolic alkalosis. This event is especially likely in a patient in whom the underlying cause of the lactic acidosis is successfully corrected (restoration of intravascular volume in a patient with severe dehydration). Once the cause of the lactic acidosis resolves, lactate can be converted by the liver into bicarbonate, which when combined with infused bicarbonate can create a metabolic alkalosis. A similar phenomenon can occur in a child with diabetic ketoacidosis

because the administration of insulin allows keto acids to be metabolized, producing bicarbonate. However, this phenomenon rarely occurs because of judicious use of bicarbonate therapy in diabetic ketoacidosis and because there are usually significant pretreatment losses of keto acids in the urine, preventing massive regeneration of bicarbonate. Base administration is most likely to cause a metabolic alkalosis in patients who have an impaired ability to excrete bicarbonate in the urine. This impairment occurs in patients with concurrent volume depletion or renal insufficiency.

Clinical Manifestations

The symptoms in patients with a metabolic alkalosis are often related to the underlying disease and associated electrolyte disturbances. Children with chloride-responsive causes of metabolic alkalosis often have symptoms related to volume depletion, such as thirst and lethargy. In contrast, children with chloride-unresponsive causes may have symptoms related to hypertension.

Alkalemia causes potassium to shift into the intracellular space, producing a decrease in the extracellular potassium concentration. Alkalemia leads to increased urinary losses of potassium. Increased potassium losses are present in many of the conditions that cause a metabolic alkalosis. Therefore, most patients with a metabolic alkalosis have hypokalemia, and their symptoms may be related to the hypokalemia (see Chapter 55.4).

The symptoms of a metabolic alkalosis are caused by the associated alkalemia. The magnitude of the alkalemia is related to the severity of the metabolic alkalosis and the presence of concurrent respiratory acid–base disturbances. During alkalemia, the ionized calcium concentration decreases as a result of increased binding of calcium to albumin. The decrease in the ionized calcium concentration may cause symptoms of **tetany** (carpopedal spasm).

Arrhythmias are a potential complication of a metabolic alkalosis, and the risk for arrhythmia increases if there is concomitant hypokalemia. Alkalemia increases the risk of digoxin toxicity, and antiarrhythmic medications are less effective in the presence of alkalemia. In addition, alkalemia may decrease cardiac output. A metabolic alkalosis causes a compensatory increase in the P_{CO_2} by decreasing ventilation. In patients with underlying lung disease, the decrease in ventilatory drive can cause hypoxia. In patients with normal lungs, the hypoventilation seen in severe metabolic alkalosis can cause hypoxia.

Diagnosis

Measurement of the urinary chloride concentration is the most helpful test in differentiating among the causes of a metabolic alkalosis. The urine chloride level is low in patients with a metabolic alkalosis resulting from volume depletion, unless there is a defect in renal handling of chloride. The urine chloride level is superior to the urine sodium level in assessment of volume status in patients with a metabolic alkalosis, because the normal renal response to a metabolic alkalosis is to excrete bicarbonate. Because bicarbonate is negatively charged, it can be excreted only with a cation, usually sodium and potassium. Hence, a patient with a metabolic alkalosis may excrete sodium in the urine despite the presence of volume depletion, which normally causes avid sodium retention. *The urine chloride level is usually a good indicator of volume status, and it differentiates among the chloride-resistant and chloride-responsive causes of a metabolic alkalosis.*

Diuretics and gastric losses are the most common causes of metabolic alkalosis and are usually readily apparent from the patient history. Occasionally, metabolic alkalosis, usually with hypokalemia, may be a clue to the presence of bulimia or surreptitious diuretic use (see Chapter 28). Patients with bulimia have a low urine chloride level, indicating that they have volume depletion as a result of an extrarenal etiology, but there is no alternative explanation for their volume depletion. Surreptitious diuretic use may be diagnosed by obtaining a urine toxicology screen for diuretics. The urine chloride level is increased while a patient is using diuretics but is low when the patient stops taking them. Rarely, children with mild Bartter syndrome or Gitelman syndrome are misdiagnosed as having bulimia or abusing diuretics. The urine chloride value is always elevated in Bartter syndrome and Gitelman syndrome, and the urine toxicology screen for diuretics has a negative result. Metabolic alkalosis with hypokalemia is occasionally the initial manifestation of cystic fibrosis. An elevated sweat chloride finding is diagnostic.

Patients with a metabolic alkalosis and a high urinary chloride level are subdivided according to blood pressure status. Children with normal blood pressure may have Bartter syndrome or Gitelman syndrome. Excess base administration is another diagnostic possibility, but it is usually apparent from the history. In patients with sodium bicarbonate ingestion (baking soda), which may be unreported by the parent, the metabolic alkalosis usually occurs with significant hypernatremia. In addition, unless volume depletion is superimposed, the metabolic alkalosis from base ingestion resolves itself once the source of base is eliminated.

Measuring serum concentrations of renin and aldosterone differentiates children with a metabolic alkalosis, a high urinary chloride level, and elevated blood pressure. Both renin and aldosterone are elevated in children with either renovascular disease or a renin-secreting tumor. Aldosterone is high and renin is low in patients with adrenal adenomas or hyperplasia and glucocorticoid-remediable aldosteronism. Renin and aldosterone are low in children with Cushing syndrome, Liddle syndrome, licorice ingestion, 17α-hydroxylase deficiency, 11β-hydroxylase deficiency, and 11β-hydroxysteroid dehydrogenase deficiency. An elevated 24 hr urine cortisol value is diagnostic of Cushing syndrome, which is suspected from the presence of the other classic features of this disease (see Chapter 577). Elevations of 11-deoxycorticosterone values are seen in 17α-hydroxylase deficiency and 11β-hydroxylase deficiency.

Treatment

The approach to treatment of metabolic alkalosis depends on the severity of the alkalosis and the underlying etiology. In children with a mild metabolic alkalosis ($[HCO_3^-] < 32$), intervention is often unnecessary, although this depends on the specific circumstances. In a child with congenital heart disease who is receiving a stable dose of a loop diuretic, a mild alkalosis does not require treatment. In contrast, intervention may be appropriate in a child with a worsening mild metabolic alkalosis because of nasogastric suction. The presence of a concurrent respiratory acid–base disturbance also influences therapeutic decision making. A patient with a concurrent respiratory acidosis should have some increase in bicarbonate owing to metabolic compensation; thus, the severity of the pH elevation is more important than the bicarbonate concentration. In contrast, a patient with a respiratory alkalosis and a metabolic alkalosis is at risk for severe alkalemia; treatment may be indicated, even if the increase in bicarbonate value is only mild.

Intervention is usually necessary in children with moderate or severe metabolic alkalosis. The most effective approach is to address the underlying etiology. In some children, nasogastric suction may be decreased or discontinued. Alternatively, the addition of a gastric proton pump inhibitor reduces gastric secretion and losses of HCl. Diuretics are an important cause of metabolic alkalosis, and if a change is tolerated, they should be eliminated or the dose reduced. Adequate potassium supplementation or the addition of a potassium-sparing diuretic is also helpful in a child with a metabolic alkalosis from diuretics. Potassium-sparing diuretics not only decrease renal potassium losses but, by blocking the action of aldosterone, also decrease hydrogen ion secretion in the distal nephron, increasing urinary bicarbonate excretion. Many children cannot tolerate discontinuation of diuretic therapy; thus, potassium supplementation and potassium-sparing diuretics are the principal therapeutic approach. Arginine HCl may also be used to treat chloride-responsive metabolic acidosis if sodium or potassium salts are not appropriate. Arginine HCl may raise the serum potassium levels during administration. Rarely, in cases of severe metabolic alkalosis, acetazolamide is an option. A carbonic anhydrase inhibitor, acetazolamide decreases resorption of bicarbonate in the proximal tubule, causing significant bicarbonate loss in the urine. The patient receiving this drug must be monitored closely,

because acetazolamide produces major losses of potassium in the urine and increases fluid losses, potentially necessitating a reduction in dosage of other diuretics.

Most children with a metabolic alkalosis have one of the chloride-responsive etiologies. In these situations, administration of sufficient sodium chloride and potassium chloride to correct the volume deficit and the potassium deficit is necessary to correct the metabolic alkalosis. This approach may not be an option in the child who has volume depletion due to diuretics, because volume repletion may be contraindicated. Adequate replacement of gastric losses of sodium and potassium in a child with a nasogastric tube can minimize or prevent the development of the metabolic alkalosis. With adequate intravascular volume and a normal serum potassium concentration, the kidney is able to excrete the excess bicarbonate within a couple of days.

In children with the chloride-resistant causes of a metabolic alkalosis that are associated with hypertension, volume repletion is contraindicated because it would exacerbate the hypertension and would not repair the metabolic alkalosis. Ideally, treatment focuses on eliminating the excess aldosterone effect. Adrenal adenomas can be resected, licorice intake can be eliminated, and renovascular disease can be repaired. Glucocorticoid-remediable aldosteronism, 17α-hydroxylase deficiency, and 11β-hydroxylase deficiency respond to the administration of glucocorticoids. The mineralocorticoid effect of cortisol in 11β-hydroxysteroid dehydrogenase deficiency can be decreased with the use of spironolactone, which blocks the mineralocorticoid receptor. In contrast, the metabolic alkalosis in children with Liddle syndrome does not respond to spironolactone; however, either triamterene or amiloride is effective therapy because both agents block the sodium channel that is constitutively active in Liddle syndrome.

In children with Bartter syndrome and Gitelman syndrome, therapy includes oral potassium supplementation and potassium-sparing diuretics. Children with Gitelman syndrome often require magnesium supplementation, whereas children with severe Bartter syndrome often benefit from indomethacin.

RESPIRATORY ACIDOSIS

A respiratory acidosis is an inappropriate increase in blood CO_2 (P_{CO_2}). Carbon dioxide is a byproduct of metabolism, and it is removed from the body by the lungs. During a respiratory acidosis, there is a decrease in the effectiveness of CO_2 removal by the lungs. A respiratory acidosis is secondary to either pulmonary disease, such as severe bronchiolitis, or nonpulmonary disease, such as a narcotic overdose. Even though body production of CO_2 can vary, normal lungs are able to accommodate this variation; excess production of CO_2 is not an isolated cause of a respiratory acidosis. With impairment of alveolar ventilation, the rate of body production of CO_2 may affect the severity of the respiratory acidosis, but this is usually not a significant factor.

A respiratory acidosis causes a decrease in the blood pH, but there is normally a metabolic response that partially compensates, minimizing the severity of the acidemia. The acute metabolic response to a respiratory alkalosis occurs within minutes. The metabolic compensation for an acute respiratory acidosis is secondary to titration of acid by nonbicarbonate buffers. This buffering of hydrogen ions causes a predictable increase in the serum bicarbonate concentration: Plasma bicarbonate increases by 1 for each 10 mm Hg increase in the P_{CO_2} (acute compensation).

With a chronic respiratory acidosis, there is more significant metabolic compensation and, thus, less severe acidemia than in an acute respiratory acidosis with the same increase in P_{CO_2}. During a chronic respiratory acidosis, the kidneys increase acid excretion. This response occurs over 3-4 days and causes a predictable increase in the serum bicarbonate concentration: Plasma bicarbonate increases by 3.5 for each 10 mm Hg increase in the P_{CO_2} (chronic compensation).

The increase of serum bicarbonate concentration during a chronic respiratory acidosis is associated with a decrease in body chloride. After acute correction of a chronic respiratory acidosis, the plasma bicarbonate continues to be increased, and the patient has a metabolic alkalosis. Because of the chloride deficit, this is a chloride-responsive metabolic alkalosis; it corrects once the patient's chloride deficit is replaced.

A mixed disorder is present if the metabolic compensation is inappropriate. A higher-than-expected bicarbonate value occurs in the setting of a concurrent metabolic alkalosis, and a lower-than-expected bicarbonate value occurs in the setting of a concurrent metabolic acidosis. Evaluating whether compensation is appropriate during a respiratory acidosis requires clinical knowledge of the acuity of the process, because the expected compensation is different, depending on whether the process is acute or chronic.

The P_{CO_2} cannot be interpreted in isolation to determine whether a patient has a respiratory acidosis. A respiratory acidosis is always present if a patient has acidemia and an elevated P_{CO_2}. However, an elevated P_{CO_2} also occurs as appropriate respiratory compensation for a simple metabolic alkalosis. The patient is alkalemic; this is not a respiratory acidosis. During a mixed disturbance, a patient can have a respiratory acidosis and a normal or even low P_{CO_2}. This condition may occur in a patient with a metabolic acidosis; a respiratory acidosis is present if the patient does not have appropriate respiratory compensation (the P_{CO_2} is higher than expected from the severity of the metabolic acidosis).

Etiology and Pathophysiology

The causes of a respiratory acidosis are either pulmonary or nonpulmonary (Table 55-15). CNS disorders can decrease the activity of the central respiratory center, reducing ventilatory drive. A variety of medications and illicit drugs suppress the respiratory center. The signals from the respiratory center need to be transmitted to the respiratory muscles via the nervous system. Respiratory muscle failure can be secondary to disruption of the signal from the CNS in the spinal cord, the phrenic nerve, or the neuromuscular junction. Disorders directly affecting the muscles of respiration can prevent adequate ventilation, causing a respiratory acidosis.

Mild or moderate lung disease often causes a respiratory alkalosis as a result of hyperventilation secondary to hypoxia or stimulation of lung mechanoreceptors or chemoreceptors. Only more severe lung disease causes a respiratory acidosis. Upper airway diseases, by impairing air entry into the lungs, may decrease ventilation, producing a respiratory acidosis.

Increased production of CO_2 is never the sole cause of a respiratory acidosis, but it can increase the severity of the disease in a patient with decreased ventilation of CO_2. Increased production of CO_2 occurs in patients with fever, hyperthyroidism, excess caloric intake, and high levels of physical activity. Increased respiratory muscle work also increases CO_2 production.

Clinical Manifestations

Patients with a respiratory acidosis are often tachypneic in an effort to correct the inadequate ventilation. Exceptions include patients with a respiratory acidosis resulting from CNS depression and patients who are on the verge of complete respiratory failure secondary to fatigue of the respiratory muscles.

The symptoms of respiratory acidosis are related to the severity of the hypercarbia. Acute respiratory acidosis is usually more symptomatic than chronic respiratory acidosis. Symptoms are also increased by concurrent hypoxia or metabolic acidosis. In a patient breathing room air, hypoxia is always present if a respiratory acidosis is present. The potential CNS manifestations of respiratory acidosis include anxiety, dizziness, headache, confusion, asterixis, myoclonic jerks, hallucinations, psychosis, coma, and seizures.

Acidemia, no matter the etiology, affects the cardiovascular system. An arterial pH <7.2 impairs cardiac contractility and the normal response to catecholamines, in both the heart and the peripheral vasculature. Hypercapnia causes vasodilation, most dramatically in the cerebral vasculature, but hypercapnia produces vasoconstriction of the pulmonary circulation. Respiratory acidosis increases the risk of cardiac arrhythmias, especially in a child with underlying cardiac disease.

Diagnosis

The history and physical findings often point to a clear etiology. For the obtunded patient with poor respiratory effort, evaluation of the CNS is often indicated. This may include imaging studies (CT or MRI) and, potentially, a lumbar puncture for cerebrospinal fluid analysis. A toxicology screen for illicit drugs may also be appropriate. A response to naloxone is both diagnostic and therapeutic. In many of the diseases affecting the respiratory muscles, there is evidence of weakness in other muscles. Stridor is a clue that the child may have upper airway disease. Along with a physical examination, a chest radiograph is often helpful in diagnosing pulmonary disease.

In many patients, respiratory acidosis may be multifactorial. A child with bronchopulmonary dysplasia, an intrinsic lung disease, may worsen because of respiratory muscle dysfunction caused by severe hypokalemia resulting from long-term diuretic therapy. Conversely, a child with muscular dystrophy, a muscle disease, may worsen because of aspiration pneumonia.

For a patient with respiratory acidosis, calculation of the gradient between the alveolar oxygen concentration and the arterial oxygen concentration, the A-a O_2 gradient, is useful for distinguishing between poor respiratory effort and intrinsic lung disease. The A-a O_2 gradient is increased if the hypoxemia is caused by intrinsic lung disease (see Chapter 373).

Treatment

Respiratory acidosis is best managed by treatment of the underlying etiology. In some instances, the response is very rapid, such as after the administration of naloxone to a patient with a narcotic overdose. In contrast, in the child with pneumonia, a number of days of antibiotic therapy may be required before the respiratory status improves. In many children with a chronic respiratory acidosis, there is no curative therapy, although an acute respiratory illness superimposed on a chronic respiratory condition is usually reversible.

All patients with an acute respiratory acidosis are hypoxic, and therefore need to receive supplemental oxygen. Mechanical ventilation is necessary in some children with a respiratory acidosis. Children with a significant respiratory acidosis caused by a CNS disease usually require mechanical ventilation because such a disorder is unlikely to respond quickly to therapy. In addition, hypercarbia causes cerebral vasodilation, and the increase in intracranial pressure can be dangerous in a child with an underlying CNS disease. Readily reversible CNS depression, such as from a narcotic overdose, may not require mechanical ventilation. Decisions on mechanical ventilation for other patients depend on a number of factors. Patients with severe hypercarbia—P_{CO_2} >75 mm Hg—usually require mechanical ventilation (see Chapter 71). The threshold for intubation is lower if there is concomitant metabolic acidosis, a slowly responsive underlying disease, or hypoxia that responds poorly to oxygen, or if the patient appears to be tiring and respiratory arrest seems likely.

In patients with a chronic respiratory acidosis, the respiratory drive is often less responsive to hypercarbia and more responsive to hypoxia. Hence, with chronic respiratory acidosis, excessive use of oxygen can blunt the respiratory drive and therefore increase the P_{CO_2}. In these patients, oxygen must be used cautiously.

When possible, it is best to avoid mechanical ventilation in a patient with a chronic respiratory acidosis because extubation is often difficult. However, an acute illness may necessitate mechanical ventilation in a child with a chronic respiratory acidosis. When intubation is necessary, the P_{CO_2} should be lowered only to the patient's normal baseline, and this should be done gradually. These patients normally have an elevated serum bicarbonate concentration as a result of metabolic compensation for their respiratory acidosis. A rapid lowering of the P_{CO_2} can cause a severe metabolic alkalosis, potentially leading to complications, including cardiac arrhythmias, decreased cardiac output, and decreased cerebral blood flow. In addition, prolonged mechanical ventilation at a normal P_{CO_2} causes the metabolic compensation to resolve. When the patient is subsequently extubated, the patient will no longer benefit from metabolic compensation, causing a more severe acidemia because of the respiratory acidosis.

RESPIRATORY ALKALOSIS

A respiratory alkalosis is an inappropriate reduction in the blood CO_2 concentration. This is usually secondary to hyperventilation, initially causing removal of CO_2 to surpass production. Eventually, a new steady state is achieved, with removal equaling production, albeit at a lower CO_2 tension (P_{CO_2}). A respiratory alkalosis that is not the result of hyperventilation may occur in children receiving extracorporeal membrane oxygenation or hemodialysis, with CO_2 lost directly from the blood in the extracorporeal circuit.

With a simple respiratory alkalosis, the pH increases but there is a normal metabolic response that attenuates some of the change in the blood pH. A metabolic response to an acute respiratory alkalosis occurs within minutes, mediated by hydrogen ion release from nonbicarbonate buffers. The metabolic response to an acute respiratory alkalosis is predictable: Plasma bicarbonate falls by 2 for each 10 mm Hg decrease in the P_{CO_2} (acute compensation).

A chronic respiratory alkalosis leads to more significant metabolic compensation because of the actions of the kidneys, which decrease acid secretion, producing a decrease in the serum bicarbonate concentration. Both the proximal and distal tubules decrease acid secretion. Metabolic compensation for a respiratory alkalosis develops gradually and takes 2-3 days to produce the full effect: Plasma bicarbonate falls by 4 for each 10 mm Hg decrease in the P_{CO_2} (chronic compensation).

A chronic respiratory alkalosis is the only acid–base disturbance wherein appropriate compensation may normalize the pH, albeit >7.4.

A mixed disorder is present if the metabolic compensation is inappropriate. A higher than expected bicarbonate level occurs in the setting of a concurrent metabolic alkalosis, and a lower than expected bicarbonate level occurs in the setting of a concurrent metabolic acidosis. Evaluating whether compensation is appropriate during a respiratory alkalosis requires clinical knowledge of the acuity of the process, because the expected compensation differs according to whether the process is acute or chronic.

A low P_{CO_2} value does not always indicate a respiratory alkalosis. The P_{CO_2} also decreases as part of the appropriate respiratory compensation for a metabolic acidosis; this is not a respiratory alkalosis. A metabolic acidosis is the dominant acid–base disturbance in a patient with acidemia and a low P_{CO_2}, even though there could still be a concurrent respiratory alkalosis. In contrast, a respiratory alkalosis is always present in a patient with alkalemia and a low P_{CO_2}. Even a normal P_{CO_2} value may be consistent with a respiratory alkalosis in a patient with a metabolic alkalosis because an elevated P_{CO_2} is expected as part of appropriate respiratory compensation for the metabolic alkalosis.

Etiology and Pathophysiology

A variety of stimuli can increase the ventilatory drive and cause a respiratory alkalosis (Table 55-16). Arterial hypoxemia or tissue hypoxia stimulates peripheral chemoreceptors to signal the central respiratory center in the medulla to increase ventilation. The resultant greater respiratory effort increases the oxygen content of the blood but depresses the P_{CO_2}. The effect of hypoxemia on ventilation begins when the oxygen saturation decreases to approximately 90% (P_{O_2} = 60 mm Hg), and hyperventilation increases as hypoxemia worsens. Acute hypoxia is a more potent stimulus for hyperventilation than chronic hypoxia; thus, chronic hypoxia, as occurs in cyanotic heart disease, causes a much-less-severe respiratory alkalosis than an equivalent degree of acute hypoxia. There are many causes of hypoxemia or tissue hypoxia, including primary lung disease, severe anemia, and carbon monoxide poisoning.

The lungs contain chemoreceptors and mechanoreceptors that respond to irritants and stretching and send signals to the respiratory center to increase ventilation. Aspiration or pneumonia may stimulate the chemoreceptors, whereas pulmonary edema may stimulate the mechanoreceptors. Most of the diseases that activate these receptors may also cause hypoxemia and can, therefore, potentially lead to hyperventilation via 2 mechanisms. Patients with primary lung disease may initially have a respiratory alkalosis, but worsening of the disease, combined with respiratory muscle fatigue, often causes respiratory failure and the development of a respiratory acidosis.

Hyperventilation in the absence of lung disease occurs with direct stimulation of the central respiratory center. This occurs with CNS diseases, such as meningitis, hemorrhage, and trauma. Central hyperventilation due to lesions, such as infarcts or tumors near the central respiratory center in the midbrain, increases the rate and depth of the respiratory effort. This respiratory pattern portends a poor prognosis because these midbrain lesions are frequently fatal. Systemic processes may cause centrally mediated hyperventilation. Although the exact mechanisms are not clear, liver disease causes a respiratory alkalosis that is usually proportional to the degree of liver failure. Pregnancy causes a chronic respiratory alkalosis, probably mediated by progesterone acting on the respiratory centers. Salicylates, although often causing a concurrent metabolic acidosis, directly stimulate the respiratory center to produce a respiratory alkalosis. The respiratory alkalosis during sepsis is probably due to cytokine release.

Hyperventilation may be secondary to an underlying disease that causes pain, stress, or anxiety. In psychogenic hyperventilation or in panic attacks, there is no disease process accounting for the hyperventilation. This disorder may occur in a child who has had an emotionally stressful experience. Alternatively, it may be part of a panic disorder,

especially if there are repeated episodes of hyperventilation. In such a patient, the symptoms of acute alkalemia increase anxiety, potentially perpetuating the hyperventilation.

A respiratory alkalosis is quite common in children receiving mechanical ventilation because the respiratory center is not controlling ventilation. In addition, these children may have a decreased metabolic rate and hence less CO_2 production because of sedation and paralytic medications. Normally, decreased CO_2 production and the resultant hypocapnia decrease ventilation, but this physiologic response cannot occur in a child who cannot reduce ventilatory effort.

Clinical Manifestations

The disease process that is causing the respiratory alkalosis is usually more concerning than the clinical manifestations of the respiratory alkalosis. Chronic respiratory alkalosis is usually asymptomatic because metabolic compensation decreases the magnitude of the alkalemia.

Acute respiratory alkalosis may cause chest tightness, palpitations, lightheadedness, circumoral numbness, and paresthesias of the extremities. Less-common manifestations include tetany, seizures, muscle cramps, and syncope. The lightheadedness and syncope are probably a result of the reduction in cerebral blood flow that is caused by hypocapnia. The reduction in cerebral blood flow is the rationale for using hyperventilation to treat children with increased intracranial pressure. The paresthesias, tetany, and seizures may be partially related to the reduction in ionized calcium that occurs because alkalemia causes more calcium to bind to albumin. A respiratory alkalosis also causes a mild reduction in the serum potassium level. Patients with psychogenic hyperventilation tend to be most symptomatic as a result of the respiratory alkalosis, and these symptoms, along with a sensation of breathlessness, exacerbate the hyperventilation.

Diagnosis

In many patients, hyperventilation producing a respiratory alkalosis is not clinically detectable, even with careful observation of the patient's respiratory effort. Metabolic compensation for a respiratory alkalosis causes a low serum bicarbonate concentration. When hyperventilation is not appreciated and only serum electrolytes are evaluated, there is often a presumptive diagnosis of a metabolic acidosis. If a respiratory alkalosis is suspected, only a blood gas determination can make the diagnosis.

Hyperventilation does not always indicate a primary respiratory disorder. In some patients, the hyperventilation is appropriate respiratory compensation for a metabolic acidosis. With a primary metabolic acidosis, acidemia is present and the serum bicarbonate level is usually quite low if there is clinically detectable hyperventilation. In contrast, the serum bicarbonate level never goes below 17 mEq/L as part of the metabolic compensation for acute respiratory alkalosis, and simple acute respiratory alkalosis causes alkalemia.

The etiology of a respiratory alkalosis is often apparent from the physical examination or history, and it may consist of lung disease, neurologic disease, or cyanotic heart disease. Hypoxemia is a common cause of hyperventilation, and it is important to diagnose because it suggests a significant underlying disease that requires expeditious treatment. Hypoxemia may be detected on physical examination (cyanosis) or by pulse oximetry. However, normal pulse oximetry values do not completely eliminate hypoxemia as the etiology of the hyperventilation. There are 2 reasons why pulse oximetry is not adequate for eliminating hypoxemia as a cause of a respiratory alkalosis. First, pulse oximetry is not very sensitive at detecting a mildly low arterial partial pressure of oxygen (pO_2). Second, the hyperventilation during a respiratory alkalosis causes the pO_2 to increase, possibly to a level that is not identified as abnormal by pulse oximetry. Only an arterial blood gas measurement can completely eliminate hypoxia as an explanation for a respiratory alkalosis. Along with hypoxemia, it is important to consider processes that cause **tissue hypoxia without necessarily causing hypoxemia**. Examples are carbon monoxide poisoning, severe anemia, and heart failure.

Lung disease without hypoxemia may cause hyperventilation. Although lung disease is often apparent by history or physical examination, a chest radiograph may detect more subtle disease. The patient with a pulmonary embolism may have benign chest radiograph findings, normal pO_2, and isolated respiratory alkalosis, although hypoxia may eventually occur. Diagnosis of a pulmonary embolism requires a high index of suspicion and should be considered in children without another explanation for respiratory alkalosis, especially if risk factors are present, such as prolonged bed rest and a hypercoagulable state (e.g., nephrotic syndrome or lupus anticoagulant).

Treatment

There is seldom a need for specific treatment of respiratory alkalosis. Rather, treatment focuses on the underlying disease. Mechanical ventilator settings are adjusted to correct iatrogenic respiratory alkalosis, unless the hyperventilation has a therapeutic purpose (e.g., treatment of increased intracranial pressure).

For the patient with hyperventilation secondary to anxiety, efforts should be undertaken to reassure the child, usually enlisting the parents. Along with reassurance, patients with psychogenic hyperventilation may benefit from benzodiazepines. During an acute episode of psychogenic hyperventilation, rebreathing into a paper bag increases the patient's Pco_2. Using a paper bag, instead of a plastic bag, allows adequate oxygenation but permits the CO_2 concentration in the bag to increase. The resultant increase in the patient's Pco_2 decreases the symptoms of the respiratory alkalosis that tend to perpetuate the hyperventilation. Rebreathing should be performed only once other causes of hyperventilation have been eliminated; pulse oximetry during the rebreathing is prudent.

Chapter 56

Maintenance and Replacement Therapy

Larry A. Greenbaum

Maintenance intravenous fluids are used in a child who cannot be fed enterally. Along with maintenance fluids, children may require concurrent **replacement fluids** if they have continued excessive losses, such as may occur with drainage from a nasogastric (NG) tube or with high urine output because of nephrogenic diabetes insipidus. If dehydration is present, the patient also needs to receive **deficit** replacement (see Chapter 57). A child awaiting surgery may need only maintenance fluids, whereas a child with diarrheal dehydration needs maintenance and deficit therapy and also may require replacement fluids if significant diarrhea continues.

MAINTENANCE THERAPY

Children normally have large variations in their daily intake of water and electrolytes. The only exceptions are patients who receive fixed dietary regimens orally, via a gastric tube, or as intravenous total parenteral nutrition (TPN). Healthy children can tolerate significant variations in intake because of the many homeostatic mechanisms that can adjust absorption and excretion of water and electrolytes (see Chapter 55). The calculated water and electrolyte needs that form the basis of maintenance therapy are not absolute requirements. Rather, these calculations provide reasonable guidelines for a starting point to estimate intravenous therapy. Children do not need to be started on intravenous fluids simply because their intake is being monitored in a hospital and they are not taking "maintenance fluids" orally, unless there is a pathologic process present that necessitates high fluid intake.

Table 56-1	Goals of Maintenance Fluids
Prevent dehydration Prevent electrolyte disorders Prevent ketoacidosis Prevent protein degradation	

Maintenance fluids are most commonly necessary in preoperative and postoperative surgical patients; many nonsurgical patients also require maintenance fluids. It is important to recognize when it is necessary to begin maintenance fluids. A normal teenager who is given nothing by mouth (NPO) overnight for a morning procedure does not require maintenance fluids because a healthy adolescent can easily tolerate 12 or 18 hr without oral intake. In contrast, a 6 mo old child waiting for surgery should begin receiving intravenous fluids within 8 hr of the last feeding. Infants become dehydrated more quickly than older patients. A child with obligatory high urine output from nephrogenic diabetes insipidus should begin receiving intravenous fluids soon after being classified as NPO.

Maintenance fluids are composed of a solution of water, glucose, sodium, and potassium. This solution has the advantages of simplicity, long shelf life, low cost, and compatibility with peripheral intravenous administration. Such a solution accomplishes the major objectives of maintenance fluids (Table 56-1). Patients lose water, sodium, and potassium in their urine and stool; water is also lost from the skin and lungs. Maintenance fluids replace these losses, thereby avoiding the development of dehydration and deficiency of sodium or potassium.

The glucose in maintenance fluids provides approximately 20% of the normal caloric needs of the patient, prevents the development of starvation ketoacidosis, and diminishes the protein degradation that would occur if the patient received no calories. Glucose also provides added osmoles, thus avoiding the administration of hypotonic fluids that may cause hemolysis.

Maintenance fluids do not provide adequate calories, protein, fat, minerals, or vitamins. This fact is typically not problematic for a patient receiving intravenous fluids for a few days. A patient receiving maintenance intravenous fluids is receiving inadequate calories and will lose 0.5-1% of weight each day. It is imperative that patients not remain on maintenance therapy indefinitely; TPN should be used for children who cannot be fed enterally for more than a few days, especially patients with underlying malnutrition.

Prototypical maintenance fluid therapy does not provide electrolytes such as calcium, phosphorus, magnesium, and bicarbonate. For most patients, this lack is not problematic for a few days, although there are patients who will not tolerate this omission, usually because of excessive losses. A child with renal tubular acidosis wastes bicarbonate in urine. Such a patient will rapidly become acidemic unless bicarbonate (or acetate) is added to the maintenance fluids. It is important to remember the limitations of maintenance fluid therapy.

MAINTENANCE WATER

Water is a crucial component of maintenance fluid therapy because of the obligatory daily water losses. These losses are both measurable (urine, stool) and not measurable (insensible losses from the skin and lungs). Failure to replace these losses leads to a child who is thirsty, uncomfortable, and, ultimately, dehydrated.

The goal of maintenance water is to provide enough water to replace these losses. Although urinary losses are approximately 60% of the total, the normal kidney has the ability to markedly modify water losses, with daily urine volume potentially varying by more than a factor of 20. Maintenance water is designed to provide enough water so that the kidney does not need to significantly dilute or concentrate the urine. It also provides a margin of safety, so that normal homeostatic mechanisms can adjust urinary water losses to prevent overhydration and dehydration. This adaptability obviates the need for absolute precision in determining water requirements. This fact is important, given the absence of absolute accuracy in the formulas for calculation of water needs. Table 56-2 provides a system for calculating maintenance water on the basis of the patient's weight and emphasizes the high water needs of smaller, less-mature patients. This approach is reliable, although calculations based on weight do overestimate the water needs of an overweight child, in whom it is better to base the calculations on the lean body weight, which can be estimated by using the 50th percentile of body weight for the child's height. It is also important to remember that there is an upper limit of 2.4 L/24 hr in adult-sized patients. Intravenous fluids are written as an hourly rate. The formulas in Table 56-3 enable rapid calculation of the rate of maintenance fluids.

Table 56-2 Body Weight Method for Calculating Daily Maintenance Fluid Volume

BODY WEIGHT	FLUID PER DAY
0-10 kg	100 mL/kg
11-20 kg	1,000 mL + 50 mL/kg for each kg >10 kg
>20 kg	1,500 mL + 20 mL/kg for each kg >20 kg*

*The maximum total fluid per day is normally 2,400 mL.

Table 56-3	Hourly Maintenance Water Rate
For body weight of 0-10 kg: 4 mL/kg/hr For body weight of 10-20 kg: 40 mL/hr + 2 mL/kg/hr × (wt − 10 kg) For body weight of >20 kg: 60 mL/hr + 1 mL/kg/hr × (wt − 20 kg)*	

*The maximum fluid rate is normally 100 mL/hr.

Table 56-4 Composition of Intravenous Solutions

FLUID	[Na]	[Cl⁻]	[K⁺]	[Ca²⁺]	[LACTATE−]
Normal saline (0.9% NaCl)	154	154	—	—	—
Half-normal saline (0.45% NaCl)	77	77	—	—	—
0.2 normal saline (0.2% NaCl)	34	34	—	—	—
Ringer lactate	130	109	4	3	28

INTRAVENOUS SOLUTIONS

The components of the commonly available solutions are shown in Table 56-4. Normal saline (NS) and Ringer lactate (LR) are isotonic solutions; they have approximately the same tonicity as plasma. Isotonic fluids without glucose are used for the acute correction of intravascular volume depletion (see Chapter 57). *The usual choices for maintenance fluid therapy in children are half-normal saline (1/2 NS) and NS.* These solutions are available with 5% dextrose (D5) or without dextrose. In addition, they are available with 20 mEq/L of potassium chloride, 10 mEq/L of potassium chloride, or no potassium. A hospital pharmacy can also prepare custom-made solutions with different concentrations of sodium or potassium. In addition, other electrolytes, such as calcium, magnesium, phosphate, acetate, and bicarbonate, can be added to intravenous solutions. Custom-made solutions take time to prepare and are much more expensive than commercial solutions. The use of custom-made solutions is necessary only for patients who have underlying disorders that cause significant electrolyte imbalances. The use of commercial solutions saves time and expense.

A normal plasma osmolality is 285-295 mOsm/kg. Infusing an intravenous solution peripherally with a much lower osmolality can cause water to move into red blood cells, leading to hemolysis. Thus, intravenous fluids are generally designed to have an osmolality that is either close to 285 or greater (fluids with moderately higher osmolality do not cause problems). Thus, 0.2NS (osmolality = 68) should not be

administered peripherally, but D5 0.2NS (osmolality = 346) or D5 ½ NS + 20 mEq/L KCl (osmolality = 472) can be administered.

There is controversy about the appropriate sodium content of maintenance fluids, considering the observation that hypotonic fluids may cause hyponatremia, which may have serious sequelae. Hypotonic fluids seem more physiologic given the low sodium content of breast milk and formula. However, hospitalized children often have impaired water excretion, either as a result of volume depletion or of nonosmotic stimuli for antidiuretic hormone (ADH) production (respiratory disease, central nervous system disease, stress, pain, nausea, medications such as narcotics). Hypotonic fluids increase the risk of hyponatremia; *0.2NS is no longer recommended as a standard maintenance fluid and its use is restricted at many hospitals.*

GLUCOSE

Maintenance fluids usually contain D5, which provides 17 calories/100 mL and nearly 20% of the daily caloric needs. This level is enough to prevent ketone production and helps minimize protein degradation, but the child will lose weight on this regimen. The weight loss is the principal reason why a patient needs to be started on TPN after a few days of maintenance fluids if enteral feedings are still not possible. Maintenance fluids are also lacking in such crucial nutrients as protein, fat, vitamins, and minerals.

SELECTION OF MAINTENANCE FLUIDS

D5 ½NS + 20 mEq/L KCl is recommended in the child who is NPO and does not have volume depletion or risk factors for nonosmotic ADH production. Children with volume depletion, baseline hyponatremia, or at risk for nonosmotic ADH production (lung infections such as bronchiolitis or pneumonia; central nervous system infection) should receive D5 NS + 20 mEq/L KCl. Surgical patients typically receive isotonic fluids (NS, LR) during surgery and in the recovery room for 6-8 hr postoperatively; the rate is typically approximately two-thirds of the calculated maintenance rate, with dextrose added if clinically indicated. Subsequent maintenance fluids should be D5 NS or LR, with addition of 10-20 mEq/L of KCl based on the serum potassium and the clinical setting. Electrolytes should be measured at least daily in all children receiving more than 50% of maintenance fluids intravenously unless the child is receiving prolonged intravenous fluids (TPN).

These guidelines assume that there is no disease process present that would require an adjustment in either the volume or the electrolyte composition of maintenance fluids. Neonates, and especially premature infants, are outside of the scope of these guidelines given their unique physiology. Children with renal insufficiency may be hyperkalemic or unable to excrete potassium and may not tolerate 10 or 20 mEq/L of potassium. Patients with persistent ADH production because of an underlying disease process (syndrome of inappropriate ADH secretion, congestive heart failure, nephrotic syndrome, liver disease) should receive less than maintenance fluids. Children with meningitis are fluid restricted unless intravascular volume depletion is present (see Chapter 603.1). Treatment is individualized, and careful monitoring is critical.

In children with complicated pathophysiologic derangements, it may be necessary to empirically adjust the electrolyte composition and rate of maintenance fluids on the basis of electrolyte measurements and assessment of fluid balance. **In all children, it is critical to carefully monitor weight, urine output, and electrolytes to identify overhydration or underhydration, hyponatremia, and other electrolyte disturbances, and to then adjust the rate or composition of the intravenous solution accordingly.**

VARIATIONS IN MAINTENANCE WATER AND ELECTROLYTES

The calculation of maintenance water is based on standard assumptions regarding water losses. There are patients, however, in whom these assumptions are incorrect. To identify such situations, it is helpful to understand the source and magnitude of normal water losses. Table 56-5 lists the 3 sources of normal water loss.

Table 56-5 Sources of Water Loss

Urine: 60%
Insensible losses: ≈35% (skin and lungs)
Stool: 5%

Table 56-6 Adjustments in Maintenance Water

SOURCE	CAUSES OF INCREASED WATER NEEDS	CAUSES OF DECREASED WATER NEEDS
Skin	Radiant warmer Phototherapy Fever Sweat Burns	Incubator (premature infant)
Lungs	Tachypnea Tracheostomy	Humidified ventilator
Gastrointestinal tract	Diarrhea Emesis Nasogastric suction	—
Renal	Polyuria	Oliguria/anuria
Miscellaneous	Surgical drain Third spacing	Hypothyroidism

Urine is the most important contributor to normal water loss. Insensible losses represent approximately one-third of total maintenance water (40% in infants and closer to 25% in adolescents and adults). Insensible losses are composed of evaporative losses from the skin and lungs that cannot be quantitated. The evaporative losses from the skin do not include sweat, which would be considered an additional (sensible) source of water loss. Stool normally represents a minor source of water loss.

Maintenance water and electrolyte needs may be increased or decreased, depending on the clinical situation. This may be obvious, in the case of the infant with profuse diarrhea, or subtle, in the case of the patient who has decreased insensible losses while receiving mechanical ventilation. It is helpful to consider the sources of normal water and electrolyte losses and to determine whether any of these sources is being modified in a specific patient. It is then necessary to adjust maintenance water and electrolyte calculations.

Table 56-6 lists a variety of clinical situations that modify normal water and electrolyte losses. The skin can be a source of very significant water loss, particularly in neonates, especially premature infants, who are under radiant warmers or are receiving phototherapy. Very-low-birthweight infants can have insensible losses of 100-200 mL/kg/24 hr. Burns can result in massive losses of water and electrolytes, and there are specific guidelines for fluid management in children with burns (see Chapter 75). Sweat losses of water and electrolytes, especially in a warm climate, can also be significant. Children with cystic fibrosis have increased sodium losses from the skin. Some children with pseudohypoaldosteronism also have increased cutaneous salt losses.

Fever increases evaporative losses from the skin. These losses are somewhat predictable, leading to a 10-15% increase in maintenance water needs for each 1°C (1.8°F) increase in temperature above 38°C (100.4°F). These guidelines are for a patient with a persistent fever; a 1 hr fever spike does not cause an appreciable increase in water needs.

Tachypnea or a tracheostomy increases evaporative losses from the lungs. A humidified ventilator causes a decrease in insensible losses from the lungs and can even lead to water absorption via the lungs; a ventilated patient has a decrease in maintenance water requirements. It may be difficult to quantify the changes that take place in the individual patient in these situations.

REPLACEMENT FLUIDS

The gastrointestinal (GI) tract is potentially a source of considerable water loss. GI water losses are accompanied by electrolytes and thus may cause disturbances in intravascular volume and electrolyte concentrations. GI losses are often associated with loss of potassium, leading to hypokalemia. Because of the high bicarbonate concentration in stool, children with diarrhea usually have a metabolic acidosis, which may be accentuated if volume depletion causes hypoperfusion and a concurrent lactic acidosis. Emesis or losses from an NG tube can cause a metabolic alkalosis (see Chapter 55).

In the absence of vomiting, diarrhea, or NG drainage, GI losses of water and electrolytes are usually quite small. All GI losses are considered excessive, and the increase in the water requirement is equal to the volume of fluid losses. Because GI water and electrolyte losses can be precisely measured, it is possible to use an appropriate replacement solution.

It is impossible to predict the losses for the next 24 hr; it is better to replace excessive GI losses as they occur. The child should receive an appropriate maintenance fluid that does not consider the GI losses. The losses should then be replaced after they occur, with use of a solution with a similar electrolyte concentration as the GI fluid. The losses are usually replaced every 1-6 hr, depending on the rate of loss, with very rapid losses being replaced more frequently.

Diarrhea is a common cause of fluid loss in children. It can cause dehydration and electrolyte disorders. In the unusual patient with significant diarrhea and a limited ability to take oral fluid, it is important to have a plan for replacing excessive stool losses. The volume of stool should be measured, and an equal volume of replacement solution should be given. Data are available on the average electrolyte composition of diarrhea in children (Table 56-7). With use of this information, it is possible to design an appropriate replacement solution. The solution shown in Table 56-7 replaces stool losses of sodium, potassium, chloride, and bicarbonate. Each 1 mL of stool should be replaced by 1 mL of this solution. The average electrolyte composition of diarrhea is just an average, and there may be considerable variation. It is therefore advisable to consider measuring the electrolyte composition of a patient's diarrhea if the amount is especially excessive or if the patient's serum electrolyte levels are problematic.

Loss of gastric fluid, via either emesis or NG suction, is also likely to cause dehydration, in that most patients with either condition have impaired oral intake of fluids. Electrolyte disturbances, particularly hypokalemia and metabolic alkalosis, are also common. These complications can be avoided by judicious use of a replacement solution. The composition of gastric fluid shown in Table 56-8 is the basis for designing a replacement solution.

Patients with gastric losses frequently have hypokalemia, although the potassium concentration of gastric fluid is relatively low. The associated urinary loss of potassium is an important cause of hypokalemia in this situation (see Chapter 55). These patients may need additional potassium either in their maintenance fluids or in their replacement fluids to compensate for prior or ongoing urinary losses. Restoration of the patient's intravascular volume, by decreasing aldosterone synthesis, lessens the urinary potassium losses.

Urine output is normally the largest cause of water loss. Diseases such as renal failure and syndrome of inappropriate ADH secretion can lead to a decrease in urine volume. The patient with oliguria or anuria has a decreased need for water and electrolytes; continuation of maintenance fluids produces fluid overload. In contrast, postobstructive diuresis, the polyuric phase of acute tubular necrosis, diabetes mellitus, and diabetes insipidus increase urine production. To prevent dehydration, the patient must receive more than standard maintenance fluids when urine output is excessive. The electrolyte losses in patients with polyuria are variable. In diabetes insipidus, the urine electrolyte concentration is usually low, whereas children with diseases such as juvenile nephronophthisis and obstructive uropathy usually have increased losses of both water and sodium.

The approach to decreased or increased urine output is similar (Table 56-9). The patient receives fluids at a rate to replace insensible losses. This is accomplished by a rate of fluid administration that is 25-40% of the normal maintenance rate, depending on the patient's age. Replacing insensible losses in the anuric child will theoretically maintain an even fluid balance, with the caveat that 25-40% of the normal maintenance rate is only an estimate of insensible losses. In the individual patient, this rate is adjusted on the basis of monitoring of the patient's weight and volume status. Most children with renal insufficiency receive little or no potassium because the kidney is the principal site of potassium excretion.

For the oliguric child, it is important to add a urine replacement solution to prevent dehydration. This issue is especially important in the patient with acute renal failure, in whom output may increase slowly, potentially leading to volume depletion and worsening of renal failure if the patient remains on only insensible fluids. A replacement solution of D5 ½NS is usually appropriate initially, although its composition may have to be adjusted if urine output increases significantly.

Most children with polyuria (except in diabetes mellitus; (see Chapter 589) should be started on replacement of insensible fluid plus urine losses. This approach avoids the need to attempt to calculate the volume of urine output that is "normal" so that the patient can be given replacement fluid for the excess. In these patients, urine output is, by definition, excessive, and it is important to measure the sodium and potassium concentrations of the urine to help in formulating the urine replacement solution.

Surgical drains and chest tubes can produce measurable fluid output. These fluid losses should be replaced when they are significant. They can be measured and replaced with an appropriate replacement solution. Third space losses, which manifest as edema and ascites, are due to a shift of fluid from the intravascular space into the interstitial space. Although these losses cannot be quantitated easily, third space losses can be large and may lead to intravascular volume depletion, despite

Table 56-7	Replacement Fluid for Diarrhea

the patient's weight gain. Replacement of third space fluid is empirical but should be anticipated in patients who are at risk, such as children who have burns or abdominal surgery. Third space losses and chest tube output are isotonic; thus, they usually require replacement with an isotonic fluid, such as NS or LR. Adjustments in the amount of replacement fluid for third space losses are based on continuing assessment of the patient's intravascular volume status. Protein losses from chest tube drainage can be significant, occasionally necessitating that 5% albumin be used as a replacement solution.

Chapter 57

Deficit Therapy

Larry A. Greenbaum

Dehydration, most often caused by gastroenteritis, is a common problem in children. Most cases can be managed with oral rehydration (see Chapter 340). **Even children with mild to moderate hyponatremic or hypernatremic dehydration can be managed with oral rehydration.**

CLINICAL MANIFESTATIONS

The first step in caring for the child with dehydration is to assess the degree of dehydration (Table 57-1), which dictates both the urgency of the situation and the volume of fluid needed for rehydration. The infant with mild dehydration (3-5% of body weight dehydrated) has few clinical signs or symptoms. The infant may be thirsty; the alert parent may notice a decline in urine output. The history is most helpful. The infant with moderate dehydration has clear physical signs and symptoms. Intravascular space depletion is evident from an increased heart rate and reduced urine output. This patient needs fairly prompt intervention. The infant with severe dehydration is gravely ill. The decrease in blood pressure indicates that vital organs may be receiving inadequate perfusion. Immediate and aggressive intervention is necessary. If possible, the child with severe dehydration should initially receive intravenous therapy. For older children and adults, mild, moderate, or severe dehydration represents a lower percentage of body weight lost. This difference occurs because water accounts for a higher percentage of body weight in infants (see Chapter 55).

Clinical assessment of dehydration is only an estimate; thus, the patient must be continually reevaluated during therapy. The degree of dehydration is underestimated in hypernatremic dehydration because the movement of water from the intracellular space to the extracellular space helps preserve the intravascular volume.

Table 57-1	Clinical Evaluation of Dehydration
Mild dehydration (<5% in an infant; <3% in an older child or adult): Normal or increased pulse; decreased urine output; thirsty; normal physical findings	
Moderate dehydration (5-10% in an infant; 3-6% in an older child or adult): Tachycardia; little or no urine output; irritable/lethargic; sunken eyes and fontanel; decreased tears; dry mucous membranes; mild delay in elasticity (skin turgor); delayed capillary refill (>1.5 sec); cool and pale	
Severe dehydration (>10% in an infant; >6% in an older child or adult): Peripheral pulses either rapid and weak or absent; decreased blood pressure; no urine output; very sunken eyes and fontanel; no tears; parched mucous membranes; delayed elasticity (poor skin turgor); very delayed capillary refill (>3 sec); cold and mottled; limp, depressed consciousness	

The history usually suggests the etiology of the dehydration and may predict whether the patient will have a normal sodium concentration (isotonic dehydration), hyponatremic dehydration, or hypernatremic dehydration. The neonate with dehydration due to poor intake of breast milk often has hypernatremic dehydration. Hypernatremic dehydration is likely in any child with losses of hypotonic fluid and poor water intake, such as may occur with diarrhea, and poor oral intake because of anorexia or emesis. Hyponatremic dehydration occurs in the child with diarrhea who is taking in large quantities of low-salt fluid, such as water or formula.

Some children with dehydration are appropriately thirsty, but in others the lack of intake is part of the pathophysiology of the dehydration. Even though decreased urine output is present in most children with dehydration, good urine output may be deceptively present if a child has an underlying renal defect, such as diabetes insipidus or a salt-wasting nephropathy, or in infants with hypernatremic dehydration.

Physical examination findings are usually proportional to the degree of dehydration. Parents may be helpful in assessment of the child for the presence of sunken eyes, because this finding may be subtle. Pinching and gently twisting the skin of the abdominal or thoracic wall detects tenting of the skin (turgor, elasticity). Tented skin remains in a pinched position rather than springing quickly back to normal. It is difficult to properly assess tenting of the skin in premature infants or severely malnourished children. Activation of the sympathetic nervous system causes tachycardia in children with intravascular volume depletion; diaphoresis may also be present. Postural changes in blood pressure are often helpful for evaluating and assessing the response to therapy in children with dehydration. Tachypnea in children with dehydration may be present secondary to a metabolic acidosis from stool losses of bicarbonate or due to lactic acidosis from shock (see Chapter 70).

LABORATORY FINDINGS

Several laboratory findings are useful for evaluating the child with dehydration. The serum sodium concentration determines the type of dehydration. Metabolic acidosis may be a result of stool bicarbonate losses in children with diarrhea, secondary renal insufficiency, or lactic acidosis from shock. The anion gap is useful for differentiating among the various causes of a metabolic acidosis (see Chapter 55). Emesis or nasogastric losses usually cause a metabolic alkalosis. The serum potassium concentration may be low as a result of diarrheal losses. In children with dehydration as a result of emesis, gastric potassium losses, metabolic alkalosis, and urinary potassium losses all contribute to hypokalemia. Metabolic acidosis, which causes a shift of potassium out of cells, and renal insufficiency may lead to hyperkalemia. A combination of mechanisms may be present; thus, it may be difficult to predict the child's acid–base status or serum potassium level from the history alone.

The blood urea nitrogen (BUN) value and serum creatinine concentration are useful in assessing the child with dehydration. Volume depletion without parenchymal renal injury may cause a disproportionate increase in the BUN with little or no change in the creatinine concentration. This condition is secondary to increased passive resorption of urea in the proximal tubule as a result of appropriate renal conservation of sodium and water. The increase in the BUN with moderate or severe dehydration may be absent or blunted in the child with poor protein intake, because urea production depends on protein degradation. The BUN may be disproportionately increased in the child with increased urea production, as occurs with a gastrointestinal bleed or with the use of glucocorticoids, which increase catabolism. A significant elevation of the creatinine concentration suggests renal insufficiency, although a small, transient increase can occur with dehydration. **Acute tubular necrosis** (acute kidney injury) (see Chapter 535) because of volume depletion is the most common etiology of renal insufficiency in a child with volume depletion, but occasionally the child may have previously undetected chronic renal insufficiency or an alternative explanation for the acute renal failure. Renal vein thrombosis is a well-described sequela of severe dehydration in infants;

possible findings include thrombocytopenia and hematuria (see Chapter 519.7).

Hemoconcentration from dehydration causes increases in hematocrit, hemoglobin, and serum proteins. These values normalize with rehydration. A normal hemoglobin concentration during acute dehydration may mask an underlying anemia. A decreased albumin level in a dehydrated patient suggests a chronic disease, such as malnutrition, nephrotic syndrome, or liver disease, or an acute process, such as capillary leak. An acute or chronic protein-losing enteropathy may also cause a low serum albumin concentration.

CALCULATION OF THE FLUID DEFICIT

Determining the fluid deficit necessitates clinical determination of the percentage of dehydration and multiplication of this percentage by the patient's weight; a child who weighs 10 kg and is 10% dehydrated has a fluid deficit of 1 L.

APPROACH TO SEVERE DEHYDRATION

The child with dehydration needs acute intervention to ensure that there is adequate tissue perfusion. This resuscitation phase requires rapid restoration of the circulating intravascular volume and treatment of shock with an isotonic solution, such as normal saline (NS) or Ringer lactate (LR) (see Chapter 70). The child is given a fluid bolus, usually 20 mL/kg of the isotonic fluid, over approximately 20 min. The child with severe dehydration may require multiple fluid boluses and may need to receive the boluses as fast as possible. In a child with a known or probable metabolic alkalosis (the child with isolated vomiting), LR should not be used because the lactate would worsen the alkalosis.

Colloids, such as blood, 5% albumin, and plasma, are rarely needed for fluid boluses. A crystalloid solution (NS or LR) is satisfactory, with both less infectious risk and lower cost. Blood is obviously indicated in the child with significant anemia or acute blood loss. Plasma is useful for children with a coagulopathy. The child with hypoalbuminemia may benefit from 5% albumin, although there is evidence that albumin infusions increase mortality in adults. The volume and the infusion rate for colloids are generally modified compared with crystalloids (see Chapters 473).

The initial resuscitation and rehydration phase is complete when the child has an adequate intravascular volume. Typically, the child shows clinical improvement, including a lower heart rate, normalization of blood pressure, improved perfusion, better urine output, and a more alert affect.

With adequate intravascular volume, it is appropriate to plan the fluid therapy for the next 24 hr. A general approach is outlined in Table 57-2, with the caveat that there are many different approaches to correcting dehydration. In isonatremic or hyponatremic dehydration, the entire fluid deficit is corrected over 24 hr; a slower approach is used for hypernatremic dehydration (discussed later). The volume of isotonic fluids that the patient has received is subtracted from this total. The remaining fluid volume is then administered over 24 hr. The potassium concentration may need to be decreased or, less commonly, increased, depending on the clinical situation. Potassium is not usually included in the intravenous fluids until the patient voids and normal renal function is documented via measurement of BUN and creatinine. Children with significant ongoing losses need to receive an appropriate replacement solution (see Chapter 56).

Table 57-2 Fluid Management of Dehydration

Fluid Management of Dehydration
Restore intravascular volume:
Normal saline: 20 mL/kg over 20 min
Repeat as needed
Calculate 24-hr fluid needs: maintenance + deficit volume
Subtract isotonic fluid already administered from 24 hr fluid needs
Administer remaining volume over 24 hr using 5% dextrose NS + 20 mEq/L KCl
Replace ongoing losses as they occur

MONITORING AND ADJUSTING THERAPY

The formulation of a plan for correcting a child's dehydration is only the beginning of management. **All calculations in fluid therapy are only approximations.** This statement is especially true for the assessment of percentage dehydration. It is equally important to monitor the patient during treatment and to modify therapy on the basis of the clinical situation. Table 57-3 lists the cornerstones of patient monitoring. The patient's vital signs are useful indicators of intravascular volume status. The child with decreased blood pressure and an increased heart rate will probably benefit from a fluid bolus. Central venous pressure is an excellent indicator of fluid status in the critically ill child with shock.

The patient's intake and output are critically important in the dehydrated child. The child who, after 8 hr of therapy, has more output than input because of continuing diarrhea needs to be started on a replacement solution. See the guidelines in Chapter 56 for selecting an appropriate replacement solution. Urine output is useful for evaluating the success of therapy. Good urine output indicates that rehydration has been successful.

Signs of dehydration on physical examination suggest the need for continued rehydration. Signs of fluid overload, such as edema and pulmonary congestion, are present in the child who is overhydrated. An accurate daily weight measurement is critical for the management of the dehydrated child. There should be a gain in weight during successful therapy.

Measurement of serum electrolyte levels at least daily is appropriate for any child who is receiving intravenous rehydration. Such a child is at risk for sodium, potassium, and acid–base disorders. It is always important to look at trends. For instance, a sodium value of 144 mEq/L is normal; but if the sodium concentration was 136 mEq/L 12 hr earlier, then there is a distinct risk that the child will be hypernatremic in 12 or 24 hr. It is advisable to be proactive in adjusting fluid therapy.

Both hypokalemia and hyperkalemia are potentially serious (see Chapter 55). Because dehydration can be associated with acute renal failure and hyperkalemia, potassium is withheld from intravenous fluids until the patient has voided. The potassium concentration in the patient's intravenous fluids is not rigidly prescribed. Rather, the patient's serum potassium level and underlying renal function are used to modify potassium delivery. The patient with an elevated creatinine value and a potassium level of 5 mEq/L does not receive any potassium until the serum potassium level decreases. Conversely, the patient with a potassium level of 2.5 mEq/L may require additional potassium.

Metabolic acidosis can be quite severe in dehydrated children. Although normal kidneys eventually correct this problem, a child with renal dysfunction may be unable to correct a metabolic acidosis, and a portion of the patient's intravenous sodium chloride may have to be replaced with sodium bicarbonate or sodium acetate.

The serum potassium level is modified by the patient's acid–base status. Acidosis increases serum potassium by causing intracellular potassium to move into the extracellular space. Thus, as acidosis is corrected, the potassium concentration decreases. Again, it is best to anticipate this problem and to monitor the serum potassium concentration and adjust potassium administration appropriately.

HYPONATREMIC DEHYDRATION

The pathogenesis of hyponatremic dehydration usually involves a combination of sodium and water loss and water retention to compensate for the volume depletion. The patient has a pathologic increase in fluid loss, and the lost fluid contains sodium. Most fluid that is lost has a lower sodium concentration, so patients with only fluid loss would have hypernatremia. Diarrhea has, on average, a sodium concentration of 50 mEq/L. Replacing diarrheal fluid with water, which has almost no sodium, causes a reduction in the serum sodium concentration. The volume depletion stimulates synthesis of antidiuretic hormone, resulting in reduced renal water excretion. Hence, the body's usual mechanism for preventing hyponatremia, renal water excretion, is blocked. The risk of hyponatremia is further increased if the volume depletion is a result of loss of fluid with a higher sodium concentration, as may occur with renal salt wasting, third space losses, or diarrhea with high sodium content (cholera).

The initial goal in treating hyponatremia is correction of intravascular volume depletion with isotonic fluid (NS or LR). An overly rapid (>12 mEq/L over the first 24 hr) or overcorrection in the serum sodium concentration (>135 mEq/L) is associated with an increased risk of **central pontine myelinolysis** (see Chapter 55). Most patients with hyponatremic dehydration do well with the same basic strategy that is outlined in Table 57-2. Again, potassium delivery is adjusted according to the initial serum potassium level and the patient's renal function. Potassium is not given until the patient voids.

The patient's sodium concentration is monitored closely to ensure appropriate correction, and the sodium concentration of the fluid is adjusted accordingly. Patients with ongoing losses require an appropriate replacement solution (see Chapter 56). Patients with neurologic symptoms (seizures) as a result of hyponatremia need to receive an acute infusion of hypertonic (3%) saline to increase the serum sodium concentration rapidly (see Chapter 55).

HYPERNATREMIC DEHYDRATION

Hypernatremic dehydration is the most dangerous form of dehydration because of complications of hypernatremia and of therapy. Hypernatremia can cause serious neurologic damage, including central nervous system hemorrhages and thrombosis. This damage appears to be secondary to the movement of water from the brain cells into the hypertonic extracellular fluid, causing brain cell shrinkage and tearing blood vessels within the brain (see Chapter 55).

The movement of water from the intracellular space to the extracellular space during hypernatremic dehydration partially protects the intravascular volume. Unfortunately, because the initial manifestations are milder, children with hypernatremic dehydration are often brought for medical attention with more profound dehydration.

Children with hypernatremic dehydration are often lethargic, and they may be irritable when touched. Hypernatremia may cause fever, hypertonicity, and hyperreflexia. More severe neurologic symptoms may develop if cerebral bleeding or thrombosis occurs.

Overly rapid treatment of hypernatremic dehydration may cause significant morbidity and mortality. Idiogenic osmoles are generated within the brain during the development of hypernatremia. These idiogenic osmoles increase the osmolality within the cells of the brain, providing protection against brain cell shrinkage caused by movement of water out of the cells and into the hypertonic extracellular fluid. They dissipate slowly during the correction of hypernatremia. With overly rapid lowering of the extracellular osmolality during the correction of hypernatremia, an osmotic gradient may be created that causes water movement from the extracellular space into the cells of the brain, producing cerebral edema. Symptoms of the resultant cerebral edema can range from seizures to brain herniation and death.

To minimize the risk of cerebral edema during the correction of hypernatremic dehydration, the serum sodium concentration should not decrease by >12 mEq/L every 24 hr. The deficits in severe hypernatremic dehydration may need to be corrected over 2-4 days (Table 57-4).

The initial resuscitation of hypernatremic dehydration requires restoration of the intravascular volume with NS. *LR should not be used because it is more hypotonic than NS and may cause too rapid a decrease in the serum sodium concentration, especially if multiple fluid boluses are necessary.*

Table 57-4 Treatment of Hypernatremic Dehydration

Restore intravascular volume:
Normal saline: 20 mL/kg over 20 min (repeat until intravascular volume restored)
Determine time for correction on basis of initial sodium concentration:
[Na] 145-157 mEq/L: 24 hr
[Na] 158-170 mEq/L: 48 hr
[Na] 171-183 mEq/L: 72 hr
[Na] 184-196 mEq/L: 84 hr
Administer fluid at constant rate over time for correction:
Typical fluid: 5% dextrose + half-normal saline (with 20 mEq/L KCl unless contraindicated)
Typical rate: 1.25-1.5 times maintenance
Follow serum sodium concentration
Adjust fluid on basis of clinical status and serum sodium concentration:
Signs of volume depletion: administer normal saline (20 mL/kg)
Sodium decreases too rapidly; either:
Increase sodium concentration of intravenous fluid
Decrease rate of intravenous fluid
Sodium decreases too slowly; either:
Decrease sodium concentration of intravenous fluid
Increase rate of intravenous fluid
Replace ongoing losses as they occur

To avoid cerebral edema during correction of hypernatremic dehydration, the fluid deficit is corrected slowly. The rate of correction depends on the initial sodium concentration (see Table 57-4). There is no general agreement on the choice or the rate of fluid for correcting hypernatremic dehydration. The choice and the rate of fluid administration are not nearly as important as vigilant monitoring of the serum sodium concentration and adjustment of the therapy according to the result (see Table 57-4). The rate of decrease of the serum sodium concentration is roughly related to the "free water" delivery, although there is considerable variation between patients. Free water is water without sodium. NS contains no free water, half-NS (½NS) is 50% free water, and water is 100% free water. Smaller patients, to achieve the same decrease in the sodium concentration, tend to need higher amounts of free water delivery per kilogram because of higher insensible fluid losses. Five percent dextrose (D5) with ½NS is usually an appropriate starting solution for a patient with hypernatremic dehydration. Some patients, especially infants with ongoing **high insensible water losses**, may need to receive D5 0.2NS, which should be used with great caution and constant monitoring. Others require D5 NS. A child with dehydration as a result of pure free water loss, as usually occurs with diabetes insipidus, usually needs a more hypotonic fluid than a child with depletion of both sodium and water due to diarrhea.

Adjustment in the sodium concentration of the intravenous fluid is the most common approach to modifying the rate of decrease in the serum concentration (see Table 57-4). For difficult-to-manage patients with severe hypernatremia, having 2 intravenous solutions (e.g., D5 ½ NS and D5 NS, both with the same concentration of potassium) at the bedside can facilitate this approach by allowing for rapid adjustments of the rates of the 2 fluids. If the serum sodium concentration decreases too rapidly, the rate of D5 NS can be increased and the rate of D5 ½ NS can be decreased by the same amount. Adjustment in the total rate of fluid delivery is another approach to modifying free water delivery. For example, if the serum sodium concentration is decreasing too slowly, the rate of the intravenous fluid can be increased, thereby increasing the delivery of free water. There is limited flexibility in modifying the rate of the intravenous fluid because patients generally should receive 1.25-1.5 times the normal maintenance fluid rate. Nevertheless, in some situations, it can be a helpful adjustment.

Because increasing the rate of the intravenous fluid increases the rate of decline of the sodium concentration, signs of volume depletion are

treated with additional isotonic fluid boluses. The serum potassium concentration and the level of renal function dictate the potassium concentration of the intravenous fluid; potassium is withheld until the patient voids. Patients with hypernatremic dehydration need an appropriate replacement solution if they have ongoing, excessive losses (see Chapter 56).

Seizures are the most common manifestation of **cerebral edema** from an overly rapid decrease of the serum sodium concentration during correction of hypernatremic dehydration. Signs of increased intracranial pressure or impending herniation may develop quite rapidly (see Chapter 68). Acutely, increasing the serum concentration via an infusion of 3% sodium chloride can reverse the cerebral edema. Each 1 mL/kg of 3% sodium chloride increases the serum sodium concentration by approximately 1 mEq/L. An infusion of 4 mL/kg often results in resolution of the symptoms. This strategy is similar to that used for treating symptomatic hyponatremia (see Chapter 55).

In patients with severe hypernatremia, oral fluids must be used cautiously. Infant formula, because of its low sodium concentration, has a high free water content, and especially if added to intravenous therapy, it may contribute to a rapid decrease in the serum sodium concentration. Less hypotonic fluid, such as an oral rehydration solution, may be more appropriate initially (see Chapter 340). If oral intake is allowed, its contribution to free water delivery must be taken into account, and adjustment in the intravenous fluid is usually appropriate. Judicious monitoring of the serum sodium concentration is critical.

Pediatric Pharmacogenetics, Pharmacogenomics, and Pharmacoproteomics

Kathleen A. Neville and J. Steven Leeder

The role of genetic factors in drug disposition and response, **pharmacogenetics**, has resulted in many examples of how variations in human genes can lead to interindividual differences in pharmacokinetics and drug response at the level of individual patients. Pharmacogenetic variability contributes to the broad range of drug responses observed in children at any given age or developmental stage; it is expected that children will benefit from the promise of **personalized medicine**—identifying the right drug for the right patient at the right time (Fig. 59-1). Numerous maturational processes occur from birth through adolescence such that utilization of information resulting from the Human Gene Project and related initiatives must take into account the changing patterns of gene expression that occur over development to improve pharmacotherapeutics in children.

PHARMACOGENETICS, PHARMACOGENOMICS, AND THE CONCEPT OF PERSONALIZED MEDICINE

The terms *pharmacogenomics* and *pharmacogenetics* tend to be used interchangeably, and precise, consensus definitions are often difficult to determine. **Pharmacogenetics** classically is defined as the study or clinical testing of genetic variations that give rise to interindividual differences in the response to drugs. The earliest examples of pharmacogenetic traits include specific adverse drug reactions, such as unusually prolonged respiratory muscle paralysis caused by succinylcholine, hemolysis associated with antimalarial therapy, and isoniazid-induced neurotoxicity, all of which are a consequence of inherited variations in enzyme activity. The importance of pharmacogenetic differences has become better understood and is exemplified by the fact that the half-lives of several drugs are more similar in monozygotic twins than in dizygotic twins. However, it is important to note that in addition to pharmacogenetic differences, environmental factors (diet, smoking status, concomitant drug or toxicant exposure), physiologic variables (age, sex, disease, pregnancy), and patient compliance all contribute to variations in drug metabolism and response. Likewise, ethnicity is another potential genetic determinant of drug variability. For example, Chinese patients who are HLA-B*1502–positive and white patients who are positive for HLA-A*3101 have an increased risk of carbamazepine-induced Stevens-Johnson syndrome; white patients who are HLA-B*5701–positive have an increased risk of hypersensitivity to abacavir (Table 59-1).

Pharmacogenomics represents the marriage of pharmacology and genomics, and can be defined as the broader application of genome-wide technologies and strategies to identify both disease processes that represent new targets for drug development and factors predictive of efficacy and risk of adverse drug reactions.

Pharmacokinetics describes temporal aspects of what the body does to a drug. It is often studied in conjunction with **pharmacodynamics**, which explores what a drug does to the body (see Chapter 60). The **pharmacokinetic** properties of a drug are determined by the genes that control the drug's disposition in the body (absorption, distribution, metabolism, excretion). Drug metabolizing enzymes and drug transporters play a particularly important role in this process (Table 59-2), and the functional consequences of genetic variations in many drug metabolizing enzymes have been described between subjects of both similar and different ethnic groups. The most common clinical manifestation of pharmacogenetic variability in drug biotransformation is an increased risk of concentration-dependent toxicity as a result of reduced clearance and consequent drug accumulation. On the other hand, rapid metabolism can lead to accumulation of a toxic metabolite, as has been reported for the hepatic conversion of codeine to morphine in 4 children ages 2-5 yr who received codeine for pain after tonsillectomy and adenoidectomy. This variant pharmacokinetics resulted in 3 deaths and 1 near-death from respiratory depression. As a result of these concerns, physicians are reminded to prescribe any drug at the lowest effective dose, for the shortest time, and only on an as-needed basis.

An equally important manifestation of this variability is lack of efficacy resulting from variations in metabolism of prodrugs. The pharmacogenetics of drug receptors and other target proteins involved in signal transduction or disease pathogenesis can also be expected to contribute significantly to interindividual variability in drug disposition and response.

Therapeutic drug monitoring programs recognize that all patients are unique and that the serum concentration-time data for an individual patient theoretically can be used to optimize pharmacotherapy. These programs have been the earliest application of personalized medicine; however, routine therapeutic drug monitoring does not necessarily translate to improved patient outcome in all situations.

The concept of **personalized medicine** is based on the premise that the wealth of information accompanying the application of genomic technologies to patient-related problems will allow for (1) stratification of patient populations according to their response to a particular medication (e.g., lack of drug efficacy or excessive toxicity), and (2) stratification of diseases into specific subtypes that are categorized according to genomic criteria and by response to particular treatments.

DEFINITION OF PHARMACOGENETIC TERMS

Genetic polymorphisms (variations) result when copies of a specific gene present within a population do not have identical nucleotide sequences. The term **allele** refers to one of a series of alternative DNA sequences for a particular gene. In humans, there are 2 copies of every gene. An individual's genotype for a given gene is determined by the set of alleles that the individual possesses. The most common form of genetic variation involves a single base change at a given location, referred to as a **single-nucleotide polymorphism (SNP)** (see Chapter 81). At the other end of the spectrum are **copy number variations,** which refer to the deletion or duplication of identical or near identical DNA sequences that may be thousands to millions of bases in size. Copy number variations occur less frequently than SNPs, but may constitute 0.5-1% of an individual's genome, and thereby contribute significantly to phenotypic variation. **Haplotypes** are collections of SNPs and other allelic variations that are located close to each other and when inherited together these create a catalog of haplotypes, or **HapMap.** When the alleles at a particular gene locus on both chromosomes are identical, a **homozygous** state exists, whereas the term **heterozygous** refers to the situation in which different alleles are present at the same gene locus. The term **genotype** refers to an individual's

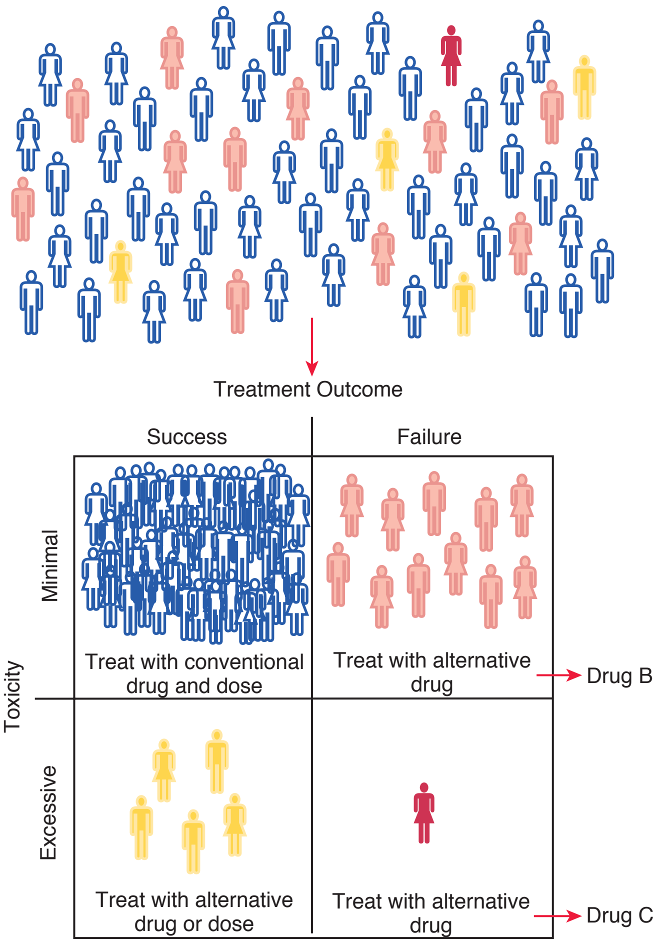

Figure 59-1 The promise of genomic medicine to human health and disease. The goal of personalized medicine will be achieved by identifying subgroups of patients who will respond favorably to a given drug with a minimum of side effects, as well as those who will not respond or who will show excessive toxicity with standard doses. A further benefit of pharmacogenomics will be the ability to select the most appropriate alternative drug for patients who cannot be treated successfully with conventional drugs and doses. *(Adapted from Yaffe SJ, Aranda JV:* Neonatal and pediatric pharmacology*, ed 3, Philadelphia, 2004, Lippincott Williams & Wilkins.)*

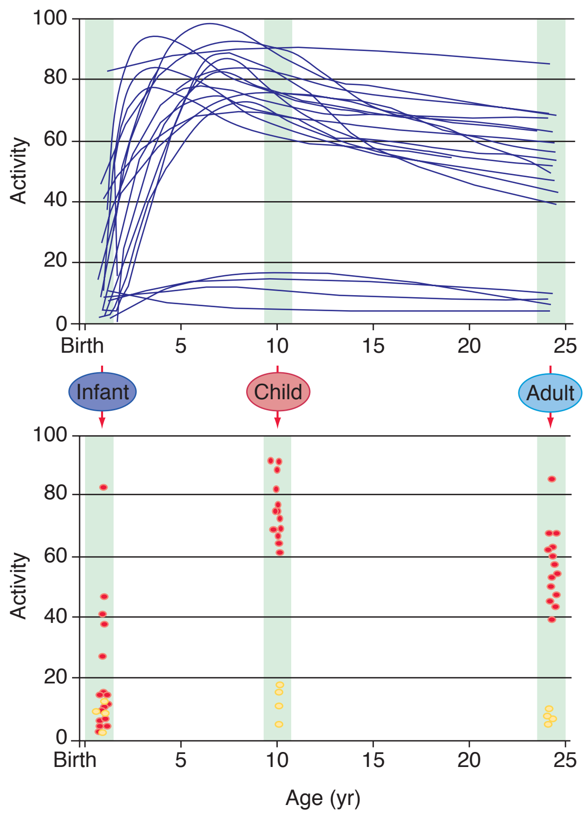

Figure 59-2 Developmental phenotypes. Variability in developmental changes in gene expression and functional enzyme activity are superimposed on pharmacogenetic determinants. The *top panel* shows the developmental profile of a theoretical drug-metabolizing enzyme over a 25 yr span in 20 subjects. At maturity (adults), allelic variation within the coding region of the gene gives rise to 2 distinct phenotypes, high activity in 92% of the population ("extensive metabolizers"; *red circles*) and low activity in 8% of the population ("poor metabolizers"; *yellow circles*). However, there is also interindividual variability in the rate at which functional activity is acquired after birth. For example, the 2 phenotypes may not be readily distinguishable in newborn infants immediately after birth. Furthermore, there may be discrete periods during childhood in which the genotype-phenotype relationship may differ from that observed in adults (e.g., developmental stages at which enzyme activity appears to be greater in children than in adults). *(Adapted from Leeder JS: Translating pharmacogenetics and pharmacogenomics into drug development for clinical pediatric and beyond.* Drug Discov Today *9:567–573, 2004.)*

genetic constitution, whereas the observable characteristics or physical manifestations constitute the **phenotype,** which is the net consequence of genetic and environmental effects (see Chapters 77-80). Pharmacogenetics focuses on the phenotypic consequences of allelic variation in single genes. **Pharmacogenetic polymorphisms** are monogenic traits that are functionally relevant to drug disposition and action and are caused by the presence (within 1 population) of more than 1 allele (at the same gene locus) and more than 1 phenotype with regard to drug interaction with the organism. The key elements of pharmacogenetic polymorphisms are heritability, the involvement of a single gene locus, functional relevance, and the fact that distinct phenotypes are observed within the population only after drug challenge.

DEVELOPMENTAL OR PEDIATRIC PHARMACOGENETICS AND PHARMACOGENOMICS

Our current understanding of pharmacogenetic principles involves enzymes responsible for drug **biotransformation.** Individuals are classified as being "fast," "rapid," or "extensive" metabolizers at one end of the spectrum, and "slow" or "poor" metabolizers at the other end of the continuum. This may or may not also include an "intermediate" metabolizer group, depending on the particular enzyme. With regard to biotransformation, children are more complex than adults as fetuses and newborns may be phenotypically "slow" or "poor" metabolizers for certain drug-metabolizing pathways because of their stage of development, and may acquire a phenotype consistent with their genotype at some point later in the developmental process as they mature. Examples of drug-metabolizing pathways that are significantly affected by ontogeny include glucuronidation and some of the cytochrome P450 (CYP) activities (see Chapters 60, 96, and 97). It is also apparent that not all infants acquire drug metabolism activity at the same rate. This is attributable to interactions between genetics and environmental factors. Interindividual variability in the trajectory (i.e., rate and extent) of acquired drug biotransformation capacity may be considered a **developmental phenotype** (Fig. 59-2), and it helps to explain the considerable variability in some CYP activities observed immediately after birth.

Pharmacogenetic, Pharmacogenomic, and Pharmacoproteomic and Metabolomic Tools

Several genotyping platforms are approved by the Food and Drug Administration and are beginning to enter the clinical arena. The Roche AmpliChip CYP450 Test was the first such device to receive FDA

Table 59-1 Examples of Effects of Gene Polymorphisms on Drug Response

GENE	ENZYME/TARGET	DRUG	CLINICAL RESPONSE
BCHE	Butyrylcholinesterase	Succinylcholine	Prolonged paralysis
CYP2C9	Cytochrome P450 2C9	Warfarin	Individuals having one or more reduced function alleles require lower doses of warfarin for optimal anticoagulation, especially initial anticoagulant control
CYP2C19	Cytochrome P450 2C19	Clopidogrel	Individuals having one or more loss-of-function alleles have reduced capacity to form the pharmacologically active metabolite of clopidogrel and reduced antiplatelet effect
CYP2D6	Cytochrome P450 2D6	Codeine	Poor metabolizers—individuals with 2 loss-of-function alleles—do not metabolize codeine to morphine and thus experience no analgesic effect; ultrarapid metabolizers (3 or more functional alleles) may experience morphine toxicity
G6PD	Glucose-6-phosphate dehydrogenase	Primaquine (others)	Hemolysis
*HLA-A*3101*	Human leukocyte antigen A31	Carbamazepine	Carriers of the *HLA-A*3101* allele have an increased risk of Stevens-Johnson syndrome and toxic epidermal necrolysis from carbamazepine
*HLA-B*1502*	Human leukocyte antigen B15	Allopurinol	Han Chinese carriers of the *HLA-B*1502* allele have an increased risk of Stevens-Johnson syndrome and toxic epidermal necrolysis from carbamazepine
*HLA-B*5701*	Human leukocyte antigen B57	Abacavir Flucloxacillin	Carriers of the *HLA-B*5701* allele have an increased risk of hypersensitivity reactions to abacavir and abacavir- and flucloxacillin-induced liver injury
*HLA-B*5801*	Human leukocyte antigen B58	Allopurinol	Carriers of the *HLA-B*5801* allele have an increased risk of severe cutaneous adverse reactions to allopurinol, including hypersensitivity reactions, Stevens-Johnson syndrome, and toxic epidermal necrolysis
NAT2	*N*-acetyltransferase 2	Isoniazid, hydralazine	Individuals homozygous for "slow acetylation" polymorphisms are more susceptible to isoniazid toxicity, or hydralazine-induced systemic lupus erythematosus
SLCO1B1	Organic anion transporting protein (OATP) 1B1	Simvastatin	Carriers of the *SLCO1B1*5* allele are at increased risk for musculoskeletal side effects from simvastatin
TPMT	Thiopurine *S*-methyltransferase	Azathioprine 6-Mercaptopurine	Individuals homozygous for an inactivating mutation have severe toxicity if treated with standard doses of azathioprine or 6-mercaptopurine; rapid metabolism causes undertreatment
UGT1A1	Uridine diphospho-glucuronosyltransferase 1A1	Irinotecan	The *UGT1A1*28* allele is associated with decreased glucuronidation of SN-38, the active metabolite of irinotecan, and increased risk of neutropenia
VKORC1	Vitamin K oxidoreductase complex 1	Warfarin	Individuals with a haplotype associated with reduced expression of the VKORC1 protein, the therapeutic target of warfarin, require lower doses of the drug for stable anticoagulation

approval, and many additional products have become available (https://www.pharmgkb.org/views/viewGeneticTests.action). In general, applications are limited to 1 or 2 genes, such as *CYP2C9* and *VKORC1* genotyping to guide warfarin therapy or genotyping of *UGT1A1* to reduce the risk of irinotecan toxicity. A more comprehensive chip that covers >90% of the absorption, distribution, metabolism, and excretion markers as defined by the PharmaADME group (http://pharmaadme.org) is available for drug development and research purposes, and the National Institute of General Medical Sciences–sponsored Pharmacogenomics Research Network has developed a list of high-priority genes of interest (http://pgrn.org/download/attachments/131165/PGRN-seq%20Gene%20List%2010-15-12%20Scherer%20Genes.pdf?version=1&modificationDate=1350681059000&api=v2).

In contrast to pharmacogenetic studies that typically target single genes, pharmacogenomic analyses are considerably broader in scope and focus on complex and highly variable drug-related phenotypes with targeting of many genes. Genomewide genotyping technologies have progressed beyond "SNP chips" to evaluate genetic variation at more than 1 million sites throughout an individual genome for SNP and copy number variation analyses to include massively parallel "next-generation sequencing" technologies. Genomewide association studies have been conducted in several pediatric settings, acute lymphoblastic leukemia, and pediatric inflammatory bowel disease. One goal of this type of study is to identify novel genes involved in disease pathogenesis that can lead to new therapeutic targets. Genomewide association studies are also being applied to identify genetic associations with response to drugs, such as warfarin and clopidogrel, and risk for drug-induced toxicity, including statin-induced myopathy and flucloxacillin hepatotoxicity. The "Manhattan plot," a form of data presentation for genomewide association studies, is common in many medical journals (Fig. 59-3*A*). Next-generation sequencing is being applied to rapidly diagnose mendelian disorders and pathologies thought to have a genetic origin when all other diagnostic approaches have been exhausted.

Investigating differential gene expression before and after drug exposure has the potential to correlate gene expression with variable drug responses and possibly uncover the mechanisms of tissue-specific drug toxicities. These types of studies use **microarray technology** or RNA-Seq (based on next-generation sequencing technologies) to monitor global changes in expression of thousands of genes (the **transcriptome**) simultaneously. The underlying hypothesis of these global

Table 59-2 Some Important Relationships Between Drugs and Cytochrome P450 (CYP) Enzymes* and P-Glycoprotein (P-gp) Transporter

gene profiling studies is that the measured signal intensity for each gene transcript represents its relative expression level; RNA-Seq allows absolute quantitation of gene expression, as well as detection of alternative splicing events. Gene expression profiling data are used to improve disease classification and risk stratification, and are utilized commonly in oncology. This approach was used to address treatment resistance in acute lymphoblastic leukemia, and has provided clinically relevant insights into the mechanistic basis of drug resistance and the genomic basis of interindividual variability in drug response. Subsets of transcripts, or gene expression "signatures," are being investigated as potential prognostic indicators for identifying patients at risk for treatment failure (Fig. 59-3*B*).

Proteomic studies use many different techniques to detect, quantify, and identify proteins in a sample **(expression proteomics),** and to

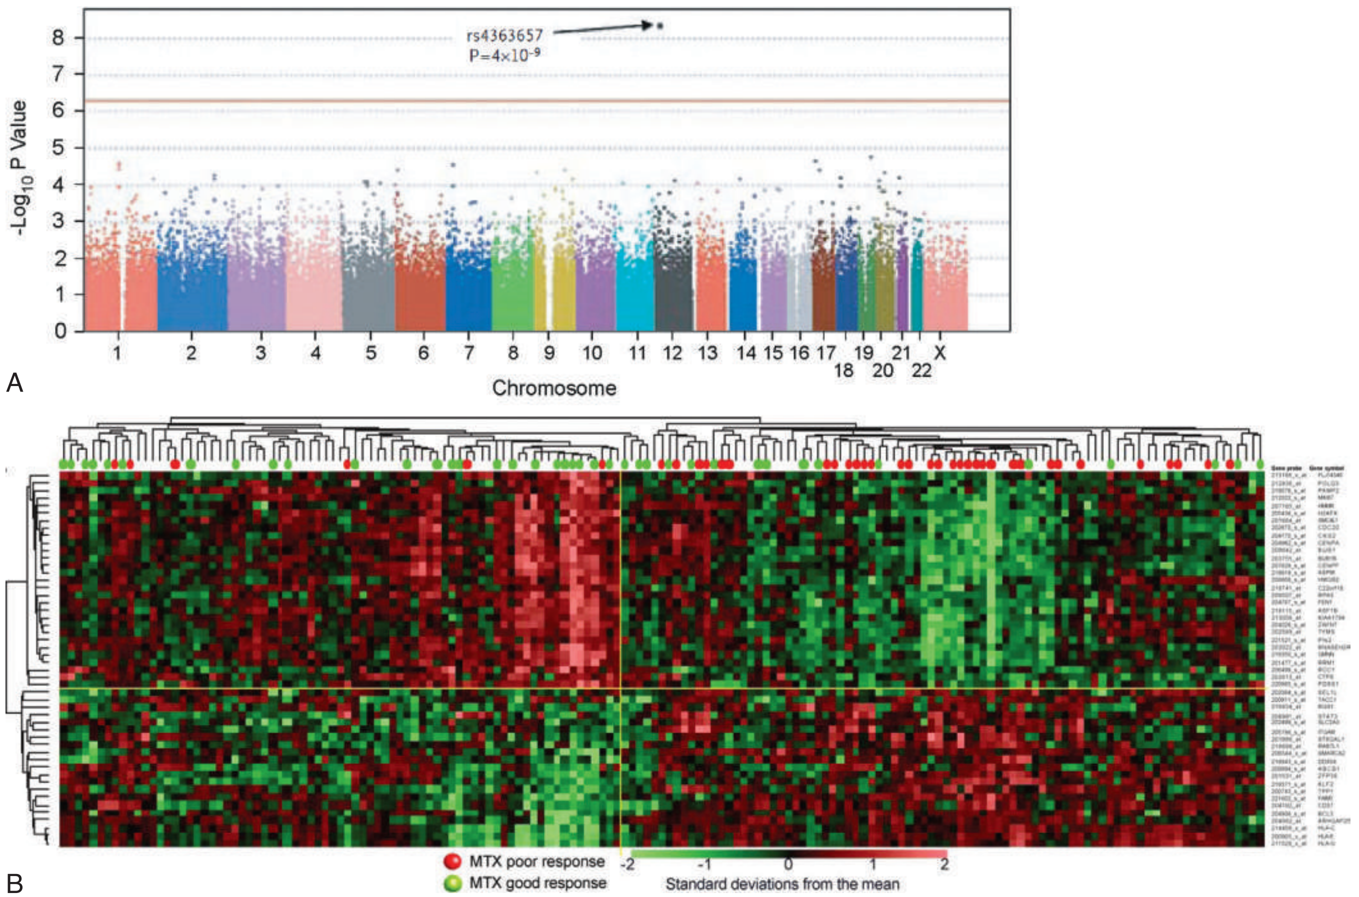

Figure 59-3 Presentations of pharmacogenomic data. **A,** Manhattan Plot from a genomewide association study. The Manhattan plot derives its name from the similarity of such a plot to the Manhattan skyline, and presents the genomewide significance of several hundred thousand SNPs distributed throughout the genome with the trait or phenotype of interest. In this example, each SNP included on the "chip" is plotted along the *x*-axis according to its chromosomal coordinate, with each color representing an individual chromosome from chromosome 1 to the X chromosome. The *y*-axis represents the inverse $\log_{10}$ of the *p* value for the association—the higher the value on the *y*-axis, the smaller the *p* value. A value of "15" corresponds to a *p* value of 10^{-15}. SNPs exceeding a particular threshold are subject to further verification and validation. **B,** "Heat map" constructed from gene expression data. In a heat map, the level of expression of many genes as obtained from microarray analysis is presented as a 2-dimensional matrix of values. Each column represents an individual patient and each row is an individual RNA transcript designated by the gene name. The level of gene expression is indicated by the color of each rectangle on a continuum from high expression *(red)* to low expression *(green).* In this example, ALL patients are clustered by their response to methotrexate, with patients responding to the drug having markedly different patterns of gene expression compared to nonresponders. One goal of personalized medicine is to use genomic information, like microarray data, to identify signatures of drug response (or risk of drug toxicity), to select the most appropriate drug among available options for each patient. *(**A** reprinted with permission from Search Collaborative Group. characterize protein function in terms of activity and protein–protein or protein–nucleic acid interactions **(functional proteomics)**. Two-dimensional electrophoresis coupled with mass spectral detection is the mainstay of expression proteomics. Protein "spots" of interest are "picked," digested with a proteolytic enzyme such as trypsin, and identified by mass spectrometry. The data generated are compared with theoretically derived peptide mass databases for protein identification.

Metabolomics and metabonomics utilize sophisticated analytical platforms, such as nuclear magnetic resonance spectroscopy and liquid or gas chromatography coupled with mass spectral detection, to measure the concentrations of all small molecules present in a sample. **Metabolomics** refers to the study of the complete set of low-molecular-weight molecules (metabolites) present in a living system (cell, tissue, organ or organism) at a particular developmental or pathological state. **Metabonomics** is defined as the study of how the metabolic profile of biological systems changes in response to alterations because of pathophysiologic stimuli, toxic exposures, dietary changes, etc. **Pharmacometabonomics** has been defined as "the prediction of the outcome, efficacy or toxicity, of a drug or xenobiotic intervention in an individual based on a mathematical model of preintervention metabolite signatures." In the future, integrating metabolomics with pharmacogenomics and transcriptomics will result in a more "systems-based" understanding of cellular processes, especially in the context of drug efficacy and toxicity.

DEVELOPMENTAL PHARMACOGENETICS OF DRUG BIOTRANSFORMATION: APPLICATIONS TO PEDIATRIC DRUG THERAPY PRACTICE

The major consequence of pharmacogenetic polymorphisms in drug metabolizing enzymes is concentration-dependent toxicity caused by impaired drug clearance. In certain cases, reduced conversion of prodrug to therapeutically active compounds is also of clinical importance (see Table 59-2). Chemical modification of drugs via biotransformation reactions generally results in termination of biologic activity through decreased affinity for receptors or other cellular targets as well as more rapid elimination from the body. The process of drug biotransformation can be very complex, but is characterized by 3 important features. First is the concept of broad **substrate specificity**—a single

isozyme may metabolize a large variety of chemically diverse compounds. Second, many different enzymes may be involved in the biotransformation of a single drug (**enzyme multiplicity**). Finally, a given drug may undergo several different types of reactions. One example of this **product multiplicity** occurs with racemic warfarin, where at least 7 different hydroxylated metabolites are produced by different CYP isoforms.

Drug biotransformation reactions are conveniently classified into 2 main types, phase I and phase II reactions, which occur sequentially and serve to terminate biologic activity and enhance elimination (see Chapter 60). Phase I reactions introduce or reveal (via oxidation, reduction, or hydrolysis) a functional group within the substrate drug molecule that serves as a site for a phase II conjugation reaction. Phase II reactions involve conjugation with endogenous substrates, such as acetate, glucuronic acid, glutathione, glycine, and sulfate. These reactions further increase the polarity of an intermediate metabolite, make the compound more water soluble and thereby enhance its renal excretion. Interindividual variability in drug biotransformation activity (for both phase I and phase II reactions) is a consequence of the complex interplay among genetic (genotype, sex, race or ethnic background) and environmental (diet, disease, concurrent medication, other xenobiotic exposure) factors. The pathway and rate of a given compound's biotransformation is a function of each individual's unique phenotype with respect to the forms and amounts of drug-metabolizing enzymes expressed.

The **CYP** enzymes are quantitatively the most important of the **phase I enzymes**. These heme-containing proteins catalyze the metabolism of many lipophilic endogenous substances (i.e., steroids, fatty acids, fat-soluble vitamins, prostaglandins, leukotrienes, and thromboxanes) as well as exogenous compounds, including a multitude of drugs and environment toxins. CYP nomenclature is based on evolutionary considerations and uses the root symbol *CYP* for *cytochrome P450.* CYP enzymes that share at least 40% homology are grouped into families denoted by an Arabic number after the *CYP* root. Subfamilies, designated by a letter, appear to represent clusters of highly related genes. Members of the human CYP2 family, for example, have >67% amino acid sequence homology. Individual P450s in a subfamily are numbered sequentially (e.g., CYP3A4, CYP3A5). CYP enzymes that have been identified as being important in human drug metabolism are predominantly found in the CYP1, CYP2, and CYP3 gene families. Importantly, enzyme activity may be induced or inhibited by various agents (see Table 59-2).

For most CYP enzymes, genotype–phenotype relationships are influenced by development in that fetal expression is limited (with the exception of CYP3A7) and functional activity is acquired postnatally in isoform-specific patterns.

Phase II enzymes include arylamine *N*-acetyltransferases (NAT1, NAT2), glucuronosyltransferases (UGTs), epoxide hydrolase, glutathione *S*-transferases, sulfotransferases, and methyltransferases (catechol *O*-methyltransferase, thiopurine *S*-methyltransferase, several *N*-methyltransferases). Like the CYPs, UGTs, sulfotransferases, and glutathione *S*-transferases are gene families with multiple individual isoforms, each having its own preferred substrates, mode of regulation, and tissue-specific pattern of expression.

Clearance of some compounds appears to be greater in children relative to adults and the correlation between genotype and phenotype in neonatal life through adolescence may be overridden by these developmental phenomena.

CYP2D6

The *CYP2D6* gene locus is highly polymorphic, with more than 100 allelic variants identified to date (http://www.cypalleles.ki.se/cyp2d6.htm; see Table 59-2). Individual alleles are designated by the gene name *(CYP2D6)* followed by an asterisk, and an Arabic number. By convention, *CYP2D6*1* designates the fully functional wild-type allele. Allelic variants are the consequence of point mutations, single base-pair deletions or additions, gene rearrangements, or deletion of the entire gene, resulting in a reduction or complete loss of activity. Inheritance of 2 recessive loss-of-function alleles results in the **poor-metabolizer phenotype,** which is found in approximately 5-10% of white subjects and approximately 1-2% of Asian subjects. In white subjects, the *3, *4, *5, and *6 alleles are the most common loss-of-function alleles and account for approximately 98% of poor-metabolizer phenotypes. In contrast, CYP2D6 activity on a population basis tends to be lower in Asian and African-American populations because of a lower frequency of nonfunctional alleles (*3, *4, *5, and *6) and a relatively high frequency of population-selective alleles that are associated with decreased activity relative to the wild-type *CYP2D6*1* allele. The *CYP2D6*10* allele occurs at a frequency of approximately 50% in Asians, whereas *CYP2D6*17* and *CYP2D6*29* occur at relatively high frequencies in subjects of black African origin.

CYP2D6 is involved in the biotransformation of more than 40 therapeutic entities, including several β-receptor antagonists, antiarrhythmics, antidepressants, antipsychotics, and morphine derivatives (for an updated list, see http://static.medicine.iupui.edu/divisions/clinpharm/content/p450_Table_Oct_11_2009.pdf; see Table 59-2). CYP2D6 substrates commonly encountered in pediatrics include selective serotonin inhibitors (SSRIs; fluoxetine, paroxetine, sertraline), risperidone, atomoxetine, promethazine, tramadol, and codeine. Furthermore, nonprescription cold remedies such as dextromethorphan, diphenhydramine and chlorpheniramine are also CYP2D6 substrates. An analysis of CYP2D6 ontogeny in vitro that utilized a relatively large number of samples revealed that CYP2D6 protein and activity remain relatively constant after 1 wk of age up to 18 yr. Similarly, results from an in vivo longitudinal phenotyping study involving more than 100 infants over the 1st year of life demonstrated considerable interindividual variability in CYP2D6 activity, but no relationship between CYP2D6 activity and postnatal age between 2 wk and 12 mo of age. Furthermore, a cross-sectional study involving 586 children reported that the distribution of CYP2D6 phenotypes in children was comparable to that observed in adults by at least 10 yr of age. Thus, both available in vitro and in vivo data, albeit based on phenotype data rather than information on drug clearance from pharmacokinetic studies, imply that genetic variation is more important than developmental factors as a determinant of CYP2D6 variability in children.

One consequence of CYP2D6 developmental pharmacogenetics may be the syndrome of irritability, tachypnea, tremors, jitteriness, increased muscle tone, and temperature instability in neonates born to mothers receiving SSRIs during pregnancy. Controversy currently exists as to whether these symptoms reflect a neonatal withdrawal (hyposerotonergic) state or represent manifestations of serotonin toxicity analogous to the hyperserotonergic state associated with the SSRI-induced serotonin syndrome in adults (see Chapter 106.1). Delayed expression of CYP2D6 (and CYP3A4) in the 1st few wk of life is consistent with a hyperserotonergic state caused by delayed clearance of paroxetine and fluoxetine (CYP2D6) or sertraline (CYP3A4) in neonates exposed to these compounds during pregnancy. Furthermore, decreases in plasma SSRI concentrations and resolution of symptoms would be expected with increasing postnatal age and maturation of these pathways. Given that treatment of a "withdrawal" reaction may include administration of an SSRI, there is considerable potential for increased toxicity in affected neonates. Resolution of the question whether symptoms are caused by withdrawal vs a hyperserotonergic state is essential for appropriate management of SSRI-induced neonatal adaptation syndromes. Until further data are available, it is prudent to consider newborns and infants younger than 28 days of age as CYP2D6 genotypic poor metabolizers.

In older children, drug accumulation and resultant concentration-dependent toxicities in CYP2D6 genotypic poor metabolizers should be anticipated in the same way that they are in adults because of the risk of significant morbidity and mortality. Although a fluoxetine-related death has been reported in a 9 yr old child with a CYP2D6 poor metabolizer genotype, experience with paroxetine indicates that the risk of drug accumulation may also occur, under certain conditions, in individuals at the opposite end of the activity spectrum. The pharmacokinetics of paroxetine and nefazodone, both CYP2D6 substrates, correlate with the CYP2D6 phenotype in children and adolescents

7-17 yr of age. However, chronic dosing of paroxetine may lead to greater-than-anticipated drug accumulation in children classified as CYP2D6 extensive metabolizers. In depressed children and adolescents, as well as in adults, there is a disproportionate increase in peak concentrations and area under the serum concentration–time curves at higher dose levels. However, nonlinearity is more prominent in patients who are CYP2D6 extensive metabolizers, especially those with gene duplications and 3 or more functional alleles. The largest decreases in paroxetine clearance observed with ascending doses are seen in patients who have the greatest clearance at the initial dose level (10 mg/day) and are predicted to have the greatest CYP2D6 activity based on CYP2D6 genotype. This seemingly paradoxical effect is best explained in the context of data from in vitro studies. One proposed mechanism involves oxidation of paroxetine within the CYP2D6 active site to form a reactive intermediate that is associated with irreversible modification of the CYP2D6 protein in or near the active site. In theory, the greater the initial CYP2D6 activity, the greater the burden of reactive metabolite burden that is formed and thereby an increased loss of CYP2D6 catalytic activity. As a consequence, as the paroxetine dose is increased in patients with higher initial drug clearance, the risk of excessive drug accumulation increases disproportionately.

Theoretically, younger children may experience decreased efficacy or therapeutic failure with drugs such as codeine and tramadol that are dependent on functional CYP2D6 activity for conversion to the pharmacologically active species. CYP2D6 catalyzes the *O*-demethylation of inactive codeine to active morphine. Infants and children appear capable of converting codeine to morphine and achieving morphine : codeine ratios comparable to those of adults. However, in one study, morphine and its metabolites were not detected in 36% of children receiving codeine, making the level of analgesia from codeine unreliable in the studied pediatric population. Interestingly, in this study levels of morphine and its metabolites were not related to CYP2D6 phenotype. Finally, ultrarapid CYP2D6 metabolism of codeine may result in opiate intoxication, including maternal ultrarapid metabolism of codeine, which can result in high serum and breast milk concentrations of morphine and may have adverse effects in the breastfed neonate.

CYP2C9

Although several clinically useful compounds are substrates for CYP2C9 (http://static.medicine.iupui.edu/divisions/clinpharm/content/p450_Table_Oct_11_2009.pdf; see Table 59-2), the effects of allelic variation are most profound for drugs with a narrow therapeutic index, such as phenytoin, warfarin, and tolbutamide. In vitro studies show a progressive increase in CYP2C9 expression from 1-2% of mature levels in the 1st trimester to approximately 30% at term. Considerable variability (approximately 35-fold) in expression is apparent over the 1st 5 mo of life, with approximately one-half of the samples studied exhibiting values equivalent to those observed in adults. One interpretation of these data is that there is broad interindividual variability in the rate at which CYP2C9 expression is acquired after birth, and in general, the ontogeny of CYP2C9 activity in vivo, as inferred from pharmacokinetic studies of phenytoin in newborns, is consistent with the in vitro results. The apparent half-life of phenytoin is prolonged (approximately 75 hr) in preterm infants, but decreases to approximately 20 hr in term newborns. By 2 wk of age, the half-life has further declined to 8 hr. Concentration-dependent (saturable) metabolism of phenytoin, reflecting the functional acquisition of CYP2C9 activity, does not appear until approximately 10 days of age. The maximal velocity of phenytoin metabolism is reported to decrease from an average of 14 mg/kg/day in infants to 8 mg/kg/day in adolescents, which may reflect changes in the ratio of liver mass to total body mass observed over this period of development, as has been observed for warfarin.

At least 56 allelic variants of *CYP2C9* have been reported, but not all have been evaluated for their functional consequences. The *CYP2C9*2* allele is associated with approximately 5.5-fold decreased intrinsic clearance for *S*-warfarin relative to the wild-type enzyme. Allelic variations resulting in amino acid changes within the enzyme active site, such as the *CYP2C9*3, CYP2C9*4,* and *CYP2C9*5* alleles, are associated with activities that are approximately 5% of the wild-type protein. Approximately one-third of the white population carries a variant *CYP2C9* allele (*2 and *3 alleles, most commonly), whereas the *2 and *3 alleles are virtually nonexistent in African-American, Chinese, Japanese, and Korean populations. In contrast, the *5 allele has been detected in African-Americans, but not in white subjects. The risk of bleeding complications in patients treated with warfarin and with concentration-dependent toxicity in patients treated with phenytoin is most pronounced for individuals with a *CYP2C9*3/*3* genotype.

Compared to adults, the pharmacogenetics of warfarin dosing has not been studied as extensively in children. In adults, genetic variation in CYP2C9 and the warfarin target,VKORC1, as well as patient age, sex and weight, can account for 50-60% of the variation in warfarin dose requirements. A large fraction of the source of variation is still unknown, but it may be at least partially attributed to interactions with other drugs and foods. Studies in children demonstrate that the contribution of *VCKORC1* and *CYP2C9* genotypes to variability in warfarin dose to achieve a stable international normalized ratio is quite variable, ranging from <5% to approximately 30%, and in each study the contribution of age, or a developmental variable that correlates with age (e.g., height or weight) accounts for the largest amount of variability. The factors contributing to differences between children and adults, and especially among the published pediatric studies, are not clear at this time.

CYP2C19

In vitro, CYP2C19 protein and catalytic activity can be detected at levels representing 12-15% of mature values by 8 wk of gestation and remain essentially unchanged throughout gestation and at birth. Over the 1st 5 mo of postnatal age, CYP2C19 activity increases linearly. Adult levels are achieved by 10 yr of age, although variability in expression is estimated to be approximately 21-fold between 5 mo and 10 yr of age. The major source of this variability is likely pharmacogenetic in nature. The CYP2C19 poor-metabolizer phenotype (also known as *mephenytoin hydroxylase deficiency*) is present in 3-5% of the white population and 20-25% of Asians. Although 25 variant alleles have been reported to date, the 2 most common variant alleles, *CYP2C19*2* and *CYP2C19*3,* result from single base substitutions that introduce premature stop codons and, consequently, truncated polypeptide chains that possess no functional activity. Despite consistent increases in CYP2C19 activity observed in vitro over the 1st 5 mo of life, the results of an in vivo phenotyping study with omeprazole in Mexican children revealed a broad range of activity and implied that 17% of infants younger than 4 mo of age could be classified as poor metabolizers (no poor metabolizers were detected beyond that point). In contrast, 20% of children 3-9 mo old were classified as ultrarapid metabolizers compared with 6% of infants 1-3 mo of age. Similarly, a series of studies investigating pantoprazole pharmacokinetics in newborns, children and adolescents has revealed that the apparent oral clearance of pantoprazole is independent of *CYP2C19* genotype in the 1st 2-3 mo after birth, but poor metabolizers can be distinguished from extensive metabolizers after 4-6 mo of age. The pharmacokinetic parameters of omeprazole are comparable to those observed in adults are achieved by 2 yr of age.

CYP2C19 also plays an important role in the metabolism of lansoprazole. In Japanese adults treated with lansoprazole, amoxicillin, and clarithromycin for *Helicobacter pylori* infection, the eradication rate for CYP2C19 poor metabolizers (97.8%) and heterozygous extensive metabolizers (1 functional *CYP2C19* allele; 92.1%) was significantly greater than that observed in homozygous extensive metabolizers (72.7%). Of the 35 patients in whom initial treatment did not eradicate *H. pylori,* 34 had at least 1 functional *CYP2C19* allele and eradication could be achieved with higher lansoprazole doses in almost all cases. Given that the frequency of the functional *CYP2C19*1* allele is considerably greater in white subjects (approximately 0.84 [84%]) compared with Japanese subjects (approximately 0.55 [55%]), eradication failure can be expected to occur more frequently in whites. Because

proton pump inhibitors are widely used in children, pharmacogenetic as well as developmental considerations should guide pediatric dosing strategies.

CYP3A4, CYP3A5, and CYP3A7

The CYP3A subfamily consists of 4 members in humans (CYPs 3A4, 3A5, 3A7, and 3A43) and is quantitatively the most important group of CYP enzymes in terms of human hepatic drug biotransformation. These isoforms catalyze the oxidation of many different therapeutic entities, several of which are of potential importance to pediatric practice (for an updated list, see http://static.medicine.iupui.edu/divisions/clinpharm/content/p450_Table_Oct_11_2009.pdf; see Table 59-2). CYP3A7 is the predominant CYP isoform in fetal liver and can be detected in embryonic liver as early as 50-60 days' gestation. CYP3A4, the major CYP3A isoform in adults, is essentially absent in fetal liver, but increases gradually throughout childhood. Over the 1st 6 mo of life, CYP3A7 expression exceeds that of CYP3A4, although its catalytic activity toward most CYP3A substrates is rather limited compared with that of CYP3A4. CYP3A4 is also abundantly expressed in intestine, where it contributes significantly to the first-pass metabolism of orally administered drugs which are substrates (i.e., midazolam). CYP3A5 is polymorphically expressed and is present in approximately 25% of adult liver samples studied in vitro.

Several methods have been proposed to measure CYP3A activity. Using these various phenotyping probes, CYP3A4 activity has been reported to vary widely (up to 50-fold) among individuals, but the population distributions of activity are essentially unimodal and evidence for polymorphic activity has been elusive. Although 24 allelic variants have been identified to date (http://www.cypalleles.ki.se/cyp3a4.htm), most occur relatively infrequently and do not appear to be of clinical importance. Of interest to pediatrics is the *CYP3A4*1B* allele present in the *CYP3A4* promoter region. The clinical significance of this allelic variant appears limited with respect to drug biotransformation activity, despite being associated with 2-fold increased activity over the wild-type *CYP3A4*1* allele in in vitro assays. Although there does not appear to be an association between the *CYP3A4*1B* allele and age of menarche, a significant relationship does exist between the number of *CYP3A4*1B* alleles and the age at onset of puberty, as defined by Tanner breast score. In one study, 90% of 9 yr old girls with a *CYP3A4*1B/*1B* genotype had a Tanner breast score of ≥2 compared with 56% of *CYP3A4*1A/*1B* heterozygotes and 40% of girls homozygous for the *CYP3A4*1A* allele. Because CYP3A4 plays an important role in testosterone catabolism, the authors of the latter study proposed that the estradiol : testosterone ratio may be shifted toward higher values in the presence of the *CYP3A4*1B* allele and trigger the hormonal cascade that accompanies puberty. Intestinal CYP3A4 activity is inhibited by grapefruit juice and may result in higher levels of the many drugs metabolized by this enzyme; very large quantities of grapefruit juice may also inhibit the hepatic CYP3A4.

The *CYP3A4*22* allele has received attention due to its association with reduced clearance of statins in adults as well as immunosuppressants, such as cyclosporine and tacrolimus, in children and adults. Improved response to inhaled fluticasone has also been reported in asthmatic children who are carriers of the *CYP3A4*22* allele.

Polymorphic *CYP3A5* expression is largely the result of a SNP in intron 3 that creates a cryptic splice site and gives rise to messenger RNA splice variants that retain part of intron 3 with a premature stop codon. The truncated messenger RNA transcripts associated with this allele, *CYP3A5*3,* cannot be translated into a functional protein. Individuals with at least 1 wild-type *CYP3A5*1* allele express functional CYP3A5 protein, whereas those homozygous for *CYP3A5*3 (CYP3A5*3/*3)* do not express appreciable amounts of functional protein. Approximately 60% of African-Americans show functional hepatic CYP3A5 activity compared with only 33% of European Americans. Clinically important consequences of *CYP3A5* allelic variation have been reported in children. In pediatric heart transplant patients with a *CYP3A5*1/*3* genotype, tacrolimus concentrations were approximately 50% of those observed in patients with *CYP3A5*3/*3* genotypes, when corrected for dose, 3 mo, 6 mo, and 12 mo after transplant. Thus, larger doses of tacrolimus are required in patients with functional CYP3A5 protein to achieve comparable blood levels and to minimize the risk of rejection.

Glucuronosyltransferases

The UGT gene superfamily catalyzes the conjugation (with glucuronic acid) of several drugs used clinically in pediatrics, including morphine, acetaminophen, nonsteroidal antiinflammatory drugs, and benzodiazepines. The effect of development on glucuronidation capacity has been well described and is illustrated by hyperbilirubinemia, **gray baby syndrome** (the cardiovascular collapse associated with high doses of chloramphenicol in newborns), and the 3.5-fold increase in morphine clearance observed in premature neonates at 24-39 wk postconceptional age. As with the CYPs, there are multiple UGT isoforms, and the acquisition of functional UGT activity appears to be isoform- and substrate-specific.

UGT1A1 is the major UGT gene product responsible for bilirubin glucuronidation, and more than 100 genetic alterations have been reported (Table 59-3), most of which are rare and are more properly considered mutations rather than gene polymorphisms (see Chapters 102 and 357.1). Inheritance of 2 defective alleles is associated with reduced bilirubin-conjugating activity and gives rise to clinical conditions, such as Crigler-Najjar syndrome and Gilbert syndrome. More frequently occurring polymorphisms involve a dinucleotide (TA) repeat in the atypical TATA box of the *UGT1A1* promoter. The wild-type *UGT1A1*1* allele has 6 repeats (TA_6), and the TA_5 *(UGT1A1*33)*, TA_7 *(UGT1A1*28)*, and TA_8 *(UGT1A1*34)* variants are all associated with reduced activity. *UGT1A1*28,* the most frequent variant, is a contributory factor to prolonged neonatal jaundice. This variant is also associated with impaired glucuronidation and thus toxicity of the active metabolite, SN-38, of the chemotherapeutic agent irinotecan. Allelic variations in *UGT1A7* and *UGT1A9* are also associated with irinotecan toxicity in adults with colorectal cancer.

The consequences of allelic variation in the *UGT2B* family are less certain. The predominant routes of morphine elimination include biotransformation to the pharmacologically active 6-glucuronide and the inactive 3-glucuronide. 6-Glucuronide formation is almost exclusively catalyzed by UGT2B7, whereas several UGTs in the UGT1A subfamily and UGT2B7 both contribute to 3-glucuronide formation. Increased 6-glucuronide : morphine ratios have been reported in individuals homozygous for the SNPs constituting the *UGT2B7*2* allele. Although individuals genotyped as *UGT2B7*2/*2* may produce higher than anticipated concentrations of pharmacologically active morphine and its metabolites, prospective pharmacogenetic studies addressing phenotype-genotype correlations and the consequences of morphine analgesia have had conflicting results.

Arylamine *N*-Acetyltransferases

One of the earliest discovered and most widely recognized genetic polymorphisms is the NAT2 polymorphism. Approximately 50% of whites and African-Americans in North America are phenotypically slow metabolizers, placing a substantial number of individuals at increased risk for the development of adverse drug effects, such as sulfasalazine-induced hemolysis, hydrazine or arylamine-induced peripheral neuropathy, procainamide- or isoniazid-induced systemic lupus erythematosus, and Stevens-Johnson syndrome or toxic epidermal necrolysis associated with sulfonamide administration. NAT2 function is inherited in an autosomal dominant fashion, with the inheritance of 2 "slow" alleles required for expression of the slow-metabolizer phenotype. The relative proportion of rapid and slow metabolizers varies considerably with ethnic or geographic origin. The percentage of slow acetylators among Canadian Eskimos is 5%, but it approaches 90% in some Mediterranean populations.

In vivo, with the use of caffeine as a phenotyping probe, all infants 0-55 days of age appear to be phenotypically slow acetylators, whereas 50% and 62% of infants 122-224 and 225-342 days of age, respectively, can be characterized as fast acetylators. Several independent studies indicate that maturation of the NAT2 phenotype occurs during the 1st 4 yr of life. Phenotype-genotype discordance is likely to be most

apparent in the 1st 2-4 mo of life, and drugs that are highly dependent on NAT2 function for their elimination should be used with caution.

Thiopurine *S*-Methyltransferase

Thiopurine *S*-methyltransferase (TPMT) is a cytosolic enzyme that catalyses the *S*-methylation of aromatic and heterocyclic sulfur-containing compounds, such as 6-mercaptopurine (6MP), azathioprine, and 6-thioguanine, used in the treatment of acute lymphoblastic leukemia (ALL), inflammatory bowel disease, juvenile arthritis, and for the prevention of renal allograft rejection. To exert its cytotoxic effects, 6MP requires metabolism to thioguanine nucleotides by a multistep process that is initiated by hypoxanthine guanine phosphoribosyl transferase. TPMT prevents thioguanine nucleotide production by methylating 6MP (Fig. 59-4*A*). TPMT activity is usually measured in erythrocytes, with activity in erythrocytes reflecting that which is found in other tissues, including liver and leukemic blasts. Although approximately 89% of whites and African-Americans have high TPMT activity and 11% have intermediate activity, 1 in 300 individuals inherit TPMT deficiency as an autosomal recessive trait (Fig. 59-4*B*). In newborn infants, peripheral blood TPMT activity is reported to be 50% greater than in race-matched adults and shows a distribution of activity that is consistent with the polymorphism characterized in adults. There are no data currently to indicate how long this higher activity is maintained, although TPMT activities were comparable to previously reported adult values in a population of Korean schoolchildren age 7-9 yr. In patients with intermediate or low activity, more drug is shunted toward production of cytotoxic thioguanine nucleotides. TPMT can also methylate 6-thioinosine 5′-monophosphate to generate a methylated metabolite that is capable of inhibiting de novo purine synthesis (Fig. 59-4*C*). Three mutations have been identified in the TPMT gene (*2, *3A, *3C), which account for 98% of white subjects with low activity. These mutations encode proteins that undergo rapid proteolysis resulting in low enzyme activity.

*TPMT*3A* is the most common mutant allele and is characterized by 2 nucleotide transition mutations, G460A and A719G, that lead to 2 amino acid substitutions, Ala154Thr and Tyr240Cys (see Fig. 59-4*D*). Although the *3A allele only has a frequency of 0.03% in the general population, it represents 55% of all mutant alleles. Either mutation alone results in loss of functional activity through the production of unstable proteins that are subject to accelerated proteolytic degradation. Less-frequent allelic variants involve SNPs that produce amino acid substitutions in the coding region and defective intron–exon splicing. A polymorphic locus has been identified in the promoter region of the *TPMT* gene involving 4-8 repeats of a specific nucleotide sequence in tandem. Although these repeats appear to modulate TPMT activity when expressed in vitro, their role in regulating activity in vivo has not been clearly established.

The relatively few patients with low to absent TPMT activity (0.3%) are at increased risk for **severe myelosuppression** if treated with routine doses of thiopurines; thus, they require a 10-15–fold reduction in dose to minimize this risk. Furthermore, if not dosed properly, patients may be at increased risk for relapse as a result of inadequate or absent treatment with thiopurines. Given the expanding use of 6MP and azathioprine in pediatrics to treat inflammatory bowel disease and juvenile arthritis and to prevent renal allograft rejection, TPMT pharmacogenetics is not a trivial matter.

Introduction of the TPMT phenotype or genotype determination into pediatric practice will lead to safer, more efficacious treatment in pediatric patient groups. Although the majority of research has been conducted in patients with acute lymphoblastic leukemia, the observation that patients classified as having intermediate TPMT activity are more likely to be intolerant of 6MP or azathioprine and likely will require more frequent dosage reductions in response to drug-induced myelosuppression is equally applicable to other pediatric patient groups (i.e., patients with Crohn disease) treated with this family of drugs.

PHARMACOGENETICS OF DRUG TRANSPORTERS

There are several major types of membrane transporters, including organic anion transporter (OAT), organic anion transporting polypeptides (OATPs), organic cation transporting proteins (OCTs), and the adenosine triphosphate–binding cassette (ABC) transporters, such as P-glycoprotein and the multidrug-resistant proteins (MRPs).

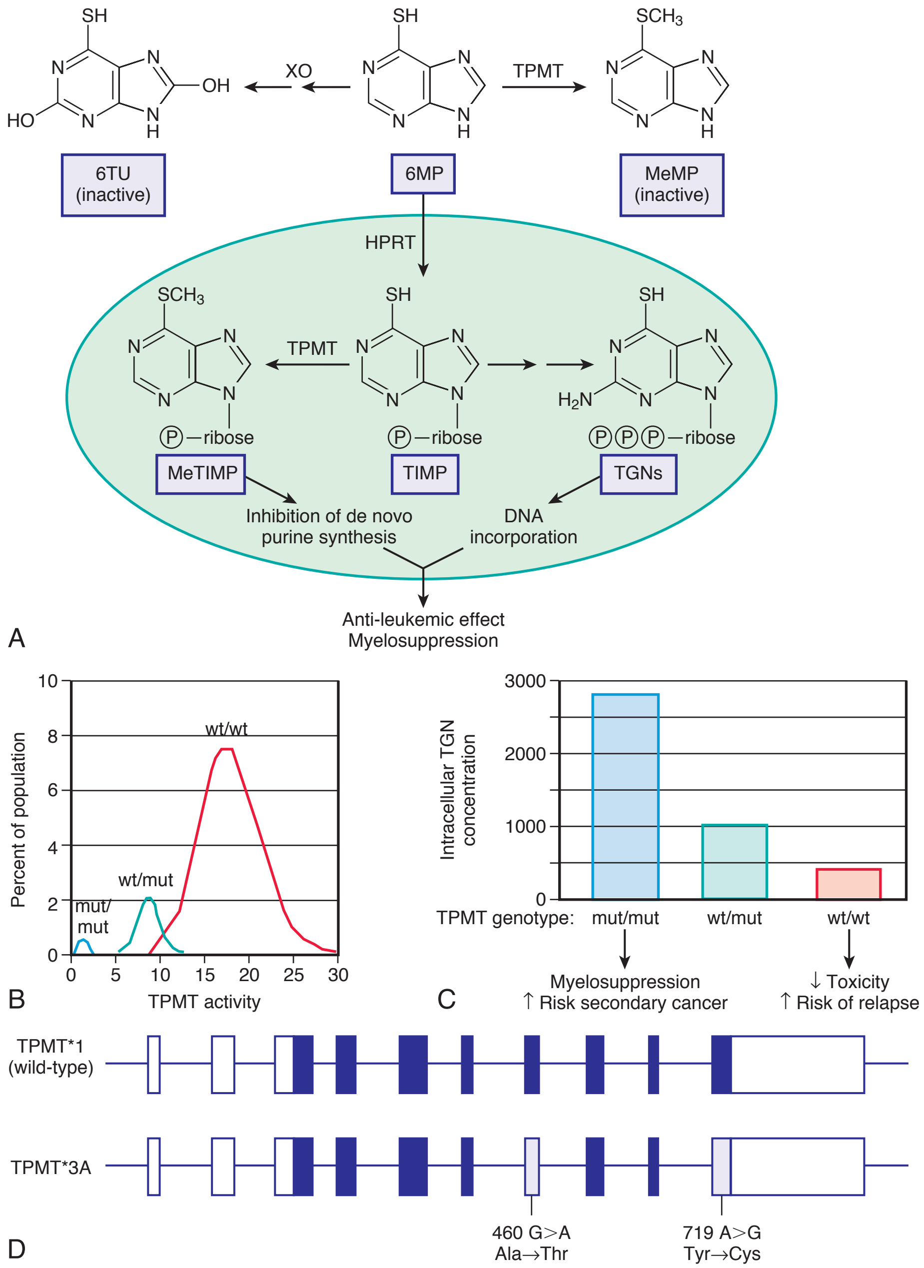

Figure 59-4 Thiopurine *S*-methyltransferase (TPMT) polymorphism. **A,** 6-Mercaptopurine (6MP) undergoes metabolism to thioguanine nucleotides (TGNs) to exert its cytotoxic effects. TPMT and xanthine oxidase reduce the amount of 6MP available for the bioactivation pathway to TGNs. TPMT can also methylate 6-thioinosine 5′-monophosphate (TIMP) to generate a methylated compound capable of inhibiting de novo purine synthesis. **B,** Distribution of TPMT activity in humans. Of the population, 89% has high activity, whereas 11% has intermediate activity. Approximately 1 in 300 individuals homozygous for 2 loss-of-function alleles has very low activity. **C,** Correlation between the TPMT genotype and intracellular TGN concentrations. In TPMT poor metabolizers, more 6MP is available to go down the bioactivation pathway to form TGNs; this situation is associated with an increased risk of myelosuppression. **D,** The most common variant TPMT allele is the result of 2 mutations that give rise to an unstable protein product that undergoes proteolytic degradation. *HPRT,* 6-thiomethylinosine 5-monophosphate; *MeMP,* 6-methylmercaptopurine; *MeTIMP,* hypoxanthine-guanine phosphoribosyl transferase; *mut,* mutant; *6TU,* 6-thiouric acid; *wt,* wild type. *(Modified with permission from Relling MV, Dervieux T: Pharmacogenetics and cancer therapy.* Nat Rev Cancer *11:99–108, 2001; copyright 2001, Macmillan Magazines Ltd.)*

Membrane transporters are heavily involved in drug disposition and actively transport substrate drugs between organs and tissues. Drug transporters are expressed at numerous epithelial barriers, such as intestinal epithelial cells, hepatocytes, renal tubular cells, and at the blood–brain barrier (Fig. 59-5). Transporters often are also determinants of drug resistance, and many drugs work by affecting the function of transporters. As such, polymorphisms in the genes encoding these proteins may have a significant effect on the absorption, distribution, metabolism, and excretion as well as the pharmacodynamic effect of a wide variety of compounds.

The Adenosine Triphosphate–Binding Cassette Superfamily

The ABC transporters belong to the largest known transporter gene family and translocate a variety of substrates, including chemotherapy agents. ABC multidrug transporter expression is implicated in tumor cell resistance to anticancer therapy, altered disposition of chemotherapy drugs, and toxic side effects associated with chemotherapy. More recently, the genetic heterogeneity of a number of the ABC transporter genes has been described. Apart from having at least 1 adenosine triphosphate (ATP)-binding domain, these transporters are

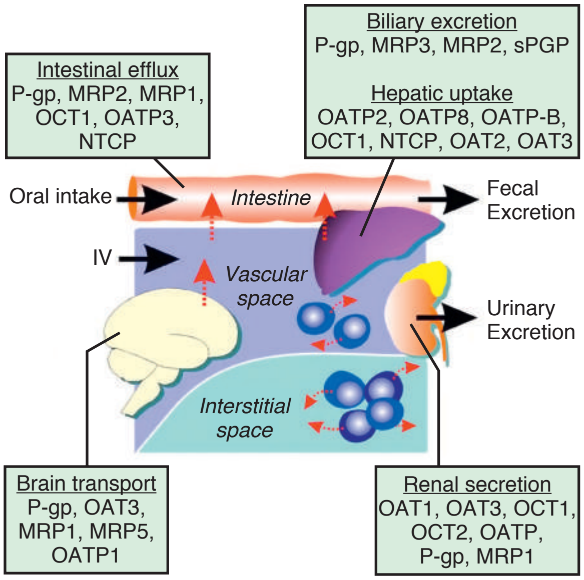

Figure 59-5 Schematic of important transport proteins and their known locations in humans. Spheres correspond to drug molecules. *(Reprinted with permission from American Pharmacists Association. Ritschel WA, Kearns GL, editors.* Handbook of basic pharmacokinetics including clinical applications, *ed 7, Washington, DC, 2009, American Pharmacists Association, p. 45.)*

characterized by a signature sequence of amino acid residues within the ATP-binding domain. In humans, the ABC transporters function as efflux pumps, which, together with detoxification enzymes, constitute a complex integrated "chemoimmunologic defense" system against drugs and other foreign chemicals. A variety of epithelial barriers, including the kidney, liver, and blood–brain barrier, have abundant expression of ABC transporters, such as P-glycoprotein (P-gp; also known as *MDR1*), and MRPs 1, 2, and 3. Powered by ATP, these transporters actively extrude substrates from the respective cell and organ.

Studies conducted in children need to also consider the ontogeny of P-gp expression. Based on studies utilizing human lymphocytes, it appears that P-gp activity is high at birth, decreases between the ages of 0 and 6 mo, and stabilizes between 6 mo and 2 yr of age. In contrast, P-gp can be detected in human neural stem/progenitor cells and decreases with differentiation. Furthermore, P-gp has been proposed as an endothelial marker for development of the blood–brain barrier, and expression increases with postnatal age as the blood–brain barrier matures. Thus, the developmental patterns of P-gp expression likely are tissue-specific, but data are very limited in this regard. Nevertheless, it is likely that expression of P-gp at a young age in gut and liver represents a protective mechanism in which both endogenous and exogenous toxins are efficiently excreted from the body. However, developmental patterns of expression in tissues of drug response, such as lymphocytes and tumors, may also affect the efficacy of intracellular drugs. For example, polymorphisms in the gene have been shown to be predictive of the ability to wean steroids after heart transplantation, as well as the susceptibility to and clinical outcome of treatment for pediatric ALL. On the other hand, immaturity of P-gp expression in the developing blood–brain barrier may contribute to discrete periods of increased susceptibility to drug toxicity in the central nervous system. However, for most other drugs, including immunosuppressants and protease inhibitors, studies investigating the effect of *ABCB1* polymorphisms in drug disposition and response have yielded conflicting results. In one study investigating the relationship between *ABCB1* genotype and cyclosporine pharmacokinetics, an effect of genotype on oral availability was only apparent in children older than 8 yr of age.

Organic Anion Transporting Polypeptides

OATPs in the solute carrier OAT (SLCO) represent a family of glycoprotein transporters with 12 transmembrane spanning domains, and are expressed in various epithelial cells. There are 11 OATPs in humans, some of which are ubiquitously expressed and others whose expression is restricted to specific tissues. Typical substrates include bile salts, hormones and their conjugates, toxins, and various drugs. The solute carrier, human OATP1A2 (OATP-A, OATP1, and OATP), is highly expressed in the intestine, kidney, cholangiocytes and the blood–brain barrier and may be important in the absorption, distribution, and excretion of a broad array of clinically important drugs. Several nonsynonymous polymorphisms have been identified in the gene encoding OATP1A2, SLCO1A2 (SLC21A3), with some of these variants demonstrating functional changes in the transport of OATP1A2 substrates.

OATP1B1 (SLCO1B1) and OATP1B3 (SLCO1B3) are liver-specific transporters and promote the cellular uptake of endogenous substrates, such as bilirubin, bile acids, dehydroepiandrosterone-sulfate and leukotriene C_4, as well as various drugs, including several statins, methotrexate, and enalapril. Allelic variation in OATP1B1 (specifically, the *SLCO1B1*5* allele) results in reduced clearance and increased systemic exposure of several statin drugs (atorvastatin, pravastatin, and simvastatin), and is associated with an increased risk of musculoskeletal side effects from simvastatin. The ontogeny of OATP1B1 has not been extensively studied in children, but the results of a small pharmacogenetic study conducted in children with familial hypercholesterolemia and pediatric cardiac transplant patients revealed an association between *SLCO1B1*5* and pravastatin concentrations that was the opposite to that observed in adults. Several studies confirm that the 2 SNPs determining the most common *SLCO1B1* haplotypes (**1a, *1b, *5,* and **15*), rs4149056 and rs2306283, are associated with decreased clearance of high-dose methotrexate in children with ALL. Genotyping for *SLCO1B1* may be helpful in identifying patients at increased risk of toxicity due to reduced clearance/increased accumulation of methotrexate, but prospective studies have not yet been conducted.

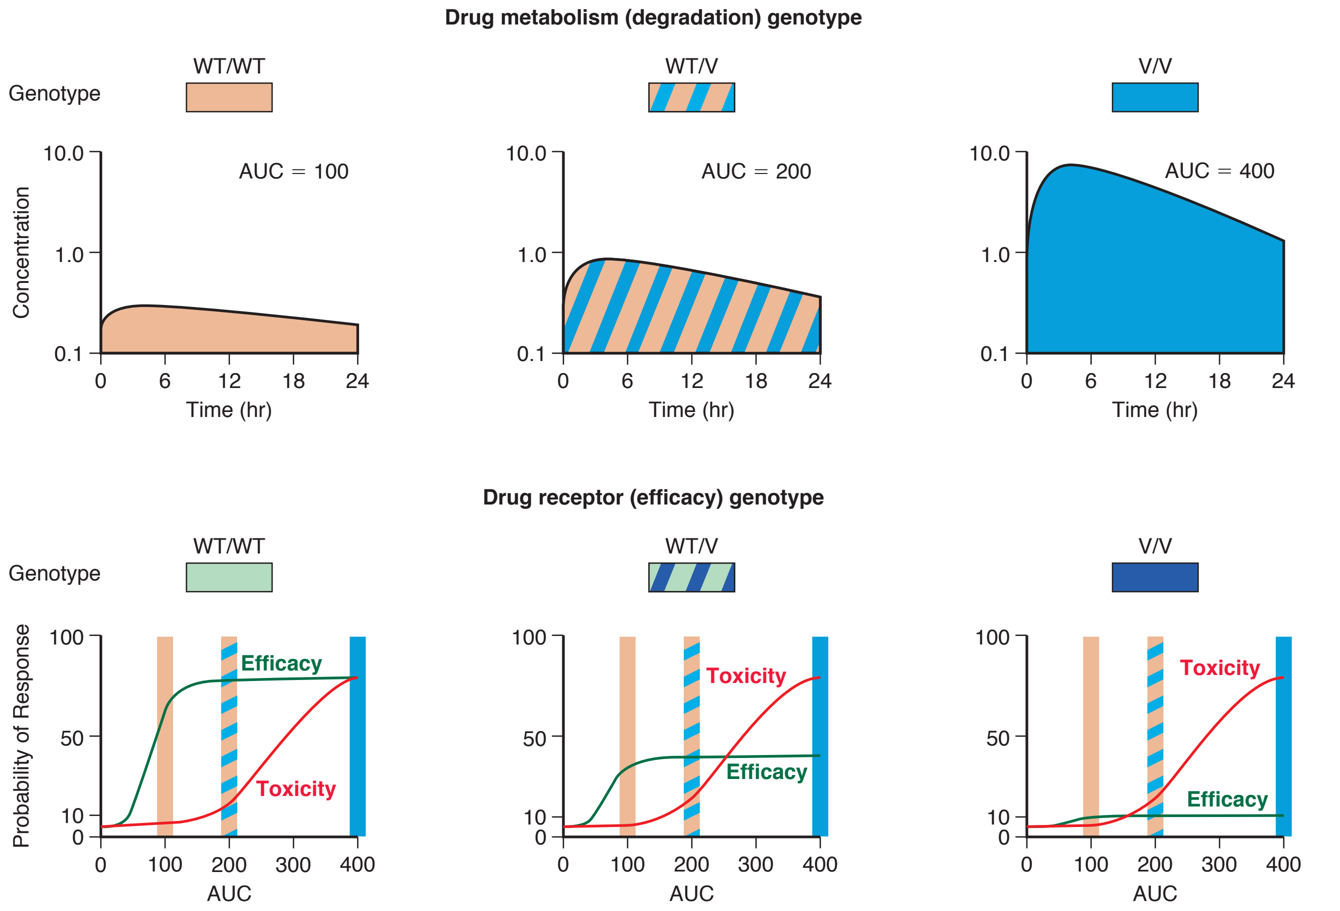
Organic Cation Transporters

OCTs in the SCL22A subfamily are primarily expressed on the basolateral membrane of polarized epithelia, and mediate the renal secretion of small organic cations. Originally, OCT1 (also known as SLC22A1) was thought to be primarily expressed in liver, but recent studies localized its expression to the apical side of proximal and distal renal tubules. OCT2 (SLC22A2) is predominantly expressed on the basolateral surface of proximal renal tubules. In adults, allelic variation in OCT1 and OCT2 is associated with increased renal clearance of metformin. The role of genetic variation of OCT1 and OCT2 has not been studied in children, but developmental factors appear to be operative. For example, neonates possess very limited ability to eliminate organic cations, but this function increases rapidly during the 1st few mo of life, and when standardized for body weight or surface area, it tends to exceed adult levels during the toddler stage.

PHARMACOGENETICS OF DRUG RESPONSE: POLYMORPHISMS IN DRUG RECEPTORS, ION CHANNELS, AND OTHER DRUG TARGETS DURING GROWTH AND DEVELOPMENT

Receptors are the targets for drugs and endogenous transmitters because of their inherent molecular recognition sites. Drugs and transmitters bind to the receptor to produce a pharmacologic effect. Variability in the receptor protein or the ion channel may determine the magnitude of the pharmacologic response. For example, polymorphisms of the β_2-adrenergic receptor gene *(ADRB2)* are associated with variable responses to bronchodilator drugs.

Drug responses are seldom monogenic events because multiple genes are involved in both drug binding to the pharmacologic target and the subsequent downstream signal transduction events that ultimately collectively manifest as a therapeutic effect. Although genotypes at a particular locus may show a statistically significant effect on the outcome of interest, they may account for only a relatively small amount of the overall population variability for that outcome. For example, a particular group of SNPs in the corticotropin-releasing hormone receptor 1 *(CRHR1)* gene is associated with a statistically



Polygenic drug response

Metabolism genotype		Receptor genotype	Probability of Response		Therapeutic Index	Individual risk : benefit assessment		
			Efficacy	Toxicity		Benefit	vs	risk

Figure 59-6 **Polygenic determinants of drug response.** The potential effects of 2 genetic polymorphisms are illustrated. In each panel, there is a profile for subjects who have 2 wild-type alleles (WT/WT), those who are heterozygous for 1 wild-type and 1 variant (V) allele (WT/V), and those who have 2 variant alleles (V/V) for the depicted gene. The *top panel* illustrates a potential polymorphism involving a drug-metabolizing enzyme where variant alleles result in decreased drug metabolism and greater exposure (as shown by the increasing area under the concentration-time curve [AUC]). The *second panel* illustrates a potential polymorphism involving a drug receptor and depicts variant alleles which result in decreased receptor sensitivity. Note that for each receptor type, there are 3 possibilities for drug exposure. At the bottom is a table that shows the 9 resulting combinations of drug-metabolism and drug-receptor genotypes and the corresponding drug-response phenotypes calculated from data shown in the second panel. These phenotypes allow for calculation of a therapeutic index (i.e., efficacy : toxicity, in this example these range from 13 [65%:5%] to 0.1 [10%:80%]), which results in the ability to perform an individualized risk : benefit assessment. *(Adapted from Evans WE, McLeod HL: Pharmacogenomics—drug disposition, drug targets, and side effects.* N Engl J Med *348:538–549, 2003.)*

significant improvement in forced expiratory volume in 1 sec, but accounts for only 6% of the overall variability in response to inhaled corticosteroids (see Chapter 144). A series of subsequent studies has determined that allelic variation in several genes in the steroid pathway contributes to overall response to this form of therapy.

The listing and classification of receptors is a major initiative of the International Union of Pharmacology. The list of receptors and voltage-gated ion channels is available on the International Union of Pharmacology website (http://www.guidetopharmacology.org/).

CURRENT AND FUTURE APPLICATIONS FOR PHARMACOGENETICS AND PHARMACOGENOMICS IN PEDIATRICS

Progress being made in the treatment of ALL provides an outstanding example of how the application of pharmacogenomic principles can improve pediatric drug therapy (see Chapter 495). Despite improved understanding of the genetic determinants of drug response, however, many complexities remain to be resolved. Patients with ALL who have 1 wild-type allele and intermediate TPMT activity tend to have a better response to 6MP therapy than patients with 2 wild-type alleles and full activity. Reduced TPMT activity also places patients at risk for irradiation-induced secondary brain tumors and etoposide-induced acute myeloid leukemias. Pharmacogenetic polymorphisms of several additional genes also have the potential to influence successful treatment of ALL. Multiple genetic and treatment-related factors interact to create patient subgroups with varying degrees of risk, and these represent an opportunity for pharmacogenomic approaches to identify subgroups of patients who will benefit from specific treatment regimens and those who will be at risk for short- and long-term toxicities (Fig. 59-6).

The 20% of patients with ALL who do not respond to chemotherapy represent an additional challenge for pharmacogenomic research. Gene expression (microarray) studies in ALL blasts are able to discriminate among phenotypic subtypes and identify some individuals who are at risk for treatment failure. An analysis of acute treatment-induced changes in the gene response of ALL blasts obtained 1 day after the initiation of 6MP and methotrexate as single agents or in combinations of high-dose or low-dose methotrexate and 6MP showed several important insights into the cellular response to these treatments. Changes in gene expression were treatment-specific and could accurately discriminate among the 4 treatments. ALL cells of different molecular subtypes shared common cellular responses to treatment, suggesting that it may be possible to personalize treatment strategies in ALL.

Chapter 60

Principles of Drug Therapy

Jennifer A. Lowry, Bridgette L. Jones, Tracy L. Sandritter, and Gregory L. Kearns

The clinical pharmacology of a given drug reflects a multifaceted set of properties that pertain to its disposition and action, and the response (e.g., adverse effects, therapeutic effects, and therapeutic outcome) to their administration/use. The 3 most important facets of the clinical pharmacology of a drug are its pharmacokinetics, pharmacodynamics, and the role of genetic variability as it may impact drug disposition or action (i.e., pharmacogenomics) (see Chapter 59).

Pharmacokinetics describes the movement of a drug throughout the body and the concentrations (or amounts) of a drug that reach a given body space and/or tissue and its residence time therein. Pharmacokinetics of a drug are conceptualized by considering those characteristics which collectively, are the determinants of the dose–concentration–effect relationship; namely, absorption, distribution, metabolism and excretion. **Pharmacodynamics** describes the relationship between drug dose or drug concentration and response. The response may be desirable *(effectiveness)* or untoward *(toxicity)*. Although in clinical practice the response to drugs in different patient populations is often described by a standard dosing or concentration range, response is best conceptualized along a continuum where the relationship between dose and response(s) are not linear. **Pharmacogenetics** is the study of how variant forms of human genes contribute to interindividual variability in either drug disposition (e.g., variant alleles of gene controlling the expression of a drug transporter) and/or response (e.g., variant alleles altering the drug–receptor interaction). The finding that drug responses can be influenced by the patient's genetic profile has offered great hope for realizing individualized pharmacotherapy when the relationship between genotype and phenotype (either disease and/or drug response) is predictive of drug response (see Chapter 59). In the developing child, it is apparent ontogeny that has the potential of modulating drug response through altering both pharmacokinetics and pharmacodynamics.

GENERAL PHARMACOKINETIC AND PHARMACODYNAMIC PRINCIPLES

Drug effect is produced only when an exposure (both amount and duration) occurs that is sufficient to produce a drug–receptor interaction capable of modulating the cellular milieu and inducing a biologic response. Thus, exposure–response relationships for a given drug represent an interface between pharmacokinetics and pharmacodynamics that can be simply conceptualized by consideration of 2 profiles: (1) plasma concentration vs effect (Fig. 60-1) and (2) plasma concentration vs time (Fig. 60-2).

The relationship between drug concentration and effect for most drugs is not linear (see Fig. 60-1). At a drug concentration of zero, the effect from the drug is generally zero or not perceptible (E_0). Following drug administration and/or with dose escalation, the concentration increases as does the effect; first in an apparent linear fashion (at low drug concentrations) followed by a nonlinear increase in effect to an asymptotic point in the relationship where a maximal effect (E_{max}) is attained that does not perceptibly change with further increases in

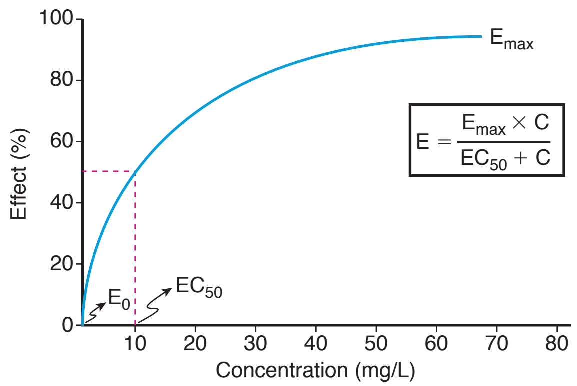

Figure 60-1 **Plasma concentration vs effect curve.** The percent effect is measured as a function of increasing drug concentration in the plasma. The dose at which no effect is seen in the population is E_0. The dose of a drug required to produce a specified effect in 50% of the population is abbreviated as EC_{50}. The concentration associated with the maximal effect that can be produced by a drug is abbreviated as E_{max}. *(From Abdel-Rahman SM, Kearns GL. The pharmacokinetic-pharmacodynamic interface: determinants of anti-infective drug action and efficacy in pediatrics. In Feigin RD, Cherry JD, Demmler-Harrison GJ, Kaplan SL, editors,* Textbook of pediatric infectious disease, *ed 6, Philadelphia, 2009, WB Saunders, pp. 3156–3178, reproduced with permission.)*

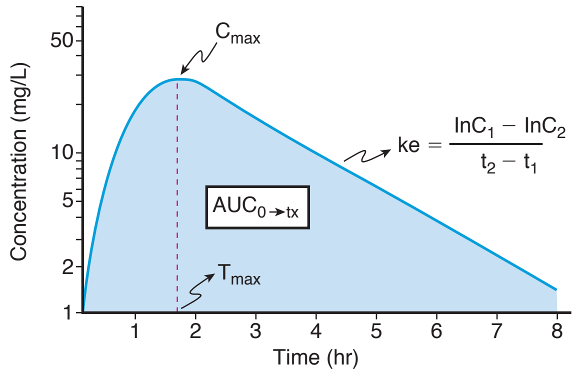

Figure 60-2 Semilogarithmic plot of the plasma concentration vs time curve for a hypothetical drug following extravascular administration. The area under the plasma level-time curve (AUC) is a concentration and time-dependent measure of systemic drug exposure. After administration, the drug is absorbed and reaches the maximal concentration (C_{max}) at its peak time (T_{max}). Following completion of drug absorption and distribution, plasma drug concentrations decline in an apparent monoexponential fashion whereby the slope of the apparent elimination phase represents the apparent elimination rate constant (ke). *(From Abdel-Rahman SM, Kearns GL. The pharmacokinetic-pharmacodynamic interface: determinants of anti-infective drug action and efficacy in pediatrics. In Feigin RD, Cherry JD, Demmler-Harrison GJ, Kaplan SL, editors,* Textbook of pediatric infectious disease, *ed 6, Philadelphia, 2009, WB Saunders, pp. 3156–3178, reproduced with permission.)*

drug concentration. The point in the concentration–effect relationship where the observed effect represents 50% of the E_{max} is defined as EC_{50}, a common pharmacodynamic term used to compare concentration–effect relationships between patients (or research subjects) and between drugs that may be in a given drug class. In practice, E_{max} can be derived either from visual interpolation of the concentration–effect profile or via mathematical curve fitting of the relationship.

Because it is rarely possible to measure drug concentrations at or near the receptor, it is necessary to utilize a surrogate measurement to assess exposure–response relationships. In most instances, this surrogate is represented by the plasma drug concentration vs time curve. For drugs whose pharmacokinetic properties are best described by 1st-order (as opposed to zero-order or mixed-order) processes, a semilogarithmic plot of plasma drug concentration vs time data for an agent given by an extravascular route of administration (e.g., intramuscular, subcutaneous, intracisternal, peroral, transmucosal, transdermal, rectal) produces a pattern similar to that illustrated by Figure 60-2. The ascending portion of this curve represents a time during which the liberation of a drug from its formulation, dissolution of the drug in a biologic fluid (e.g., gastric or intestinal fluid, interstitial fluid; a prerequisite for absorption) and absorption of a drug are rate-limiting relative to its elimination. After the time (T_{max}) where maximal plasma concentrations (C_{max}) are observed, the plasma concentration decreases as metabolism and elimination become rate limiting; the terminal portion of this segment of the plasma concentration vs time curve being representative of drug elimination from the body. Finally, the area under the plasma concentration vs time curve (AUC), a concentration- and time-dependent parameter reflective of the degree of systemic exposure from a given drug dose, can be determined by integrating the plasma concentration data over time. By being able to characterize the pharmacokinetics of a specific drug, the clinician can use the data to individualize dosing regimens for patients who by virtue of development and/or disease, must have adjustments to either the dose and/or dosing interval so as to enable the production of the degree of systemic exposure associated with desired pharmacologic effects. For drugs where a therapeutic plasma concentration range and/or "target" systemic exposure (i.e., AUC) is known, a priori knowledge of pharmacokinetic parameters for a given population or patient within a population can facilitate the selection of a drug dosing regimen. When linked with information regarding the pharmacodynamic behavior of a drug and the status of the patient (e.g., age, organ function, disease state, concomitant medications), the application of pharmacokinetics affords the practitioner the ability to exercise some real degree of adaptive control over therapeutic decision making by enabling the selection of a drug and dosing regimen that has the greatest likelihood of producing both efficacy and safety.

THE IMPACT OF ONTOGENY ON DRUG DISPOSITION

Development represents a continuum of biologic events that enable adaptation, somatic growth, neurobehavioral maturation and eventually reproduction. The impact of development on the pharmacokinetics of a given drug is determined, to a great degree, by age-related changes in body composition and the acquisition of function in organs and organ systems, which are important in determining drug metabolism and excretion. Even though it is often convenient to classify pediatric patients on the basis of postnatal age for the provision of drug therapy (e.g., neonate 0-1 mo of age; infant 1-24 mo of age; children 2-12 yr of age; and adolescents 12-18 yr of age), it is important to recognize that the changes in physiology are not linearly related to age and may not correspond to these age-defined breakpoints. In fact, the most dramatic changes in drug disposition occur during the 1st 18 mo of life where the acquisition of organ function is most dynamic. Additionally, it is important to note that the pharmacokinetics of a given drug may be altered in pediatric patients consequent to intrinsic (e.g., gender, genotype, ethnicity, inherited diseases) or extrinsic (e.g., acquired disease states, xenobiotic exposure, diet, variability in therapeutic adherence) factors that may occur during the 1st 2 decades of life.

During development, certain stages of life profoundly influence drug response and disposition. Dramatic pharmacokinetic, pharmacodynamic, and psychosocial changes occur as preterm infants mature toward term, as infants mature through the 1st few years of life, and as children reach puberty and adolescence (Fig. 60-3). It is most useful to conceptualize the impact of ontogeny on drug disposition by considering its specific facets, namely, drug absorption, distribution, metabolism, and excretion, as well as ontogeny's impact on drug action (pharmacodynamics).

Drug Absorption

Absorption usually occurs via passive diffusion, but active transport or facilitated diffusion also may be necessary for drug entry into cells. Several physiologic factors affect this process, 1 or more of which may be altered in the face of certain disease states (e.g., inflammatory bowel disease, diarrhea) and, consequently, produce changes in drug bioavailability. The rate and extent of absorption can be significantly affected as a consequence of a child's normal growth and development.

Peroral Absorption

The most important factors that influence drug absorption from the gastrointestinal tract are related to the physiology of the stomach, intestine, and biliary tract (see Fig. 60-3C and Table 60-1). The rate and extent of peroral absorption of drugs depends primarily on the pH-dependent passive diffusion and motility of the stomach and intestinal tract as both of these factors will influence transit time of the drug. Gastric pH changes significantly throughout development with the highest (alkaline) values occurring during the neonatal period. In the fully mature neonate, the gastric pH ranges from 6-8 at birth and drops to 2-3 within a few hours of birth. However, after the 1st 24 hr of life, the gastric pH drifts upward because of the immaturity of the parietal cells. As the parietal cells mature, the gastric acid secretory capacity increases (pH decreases) over the 1st few months of life to reach consistent adult levels by 3-7 yr of age. As a result, the peroral bioavailability of acid-labile drugs, such as penicillin or ampicillin, is increased. In contrast, the absorption of weak organic acids (e.g., phenobarbital and phenytoin) is relatively decreased, a condition which may necessitate the administration of larger doses in the very young to achieve therapeutic plasma levels.

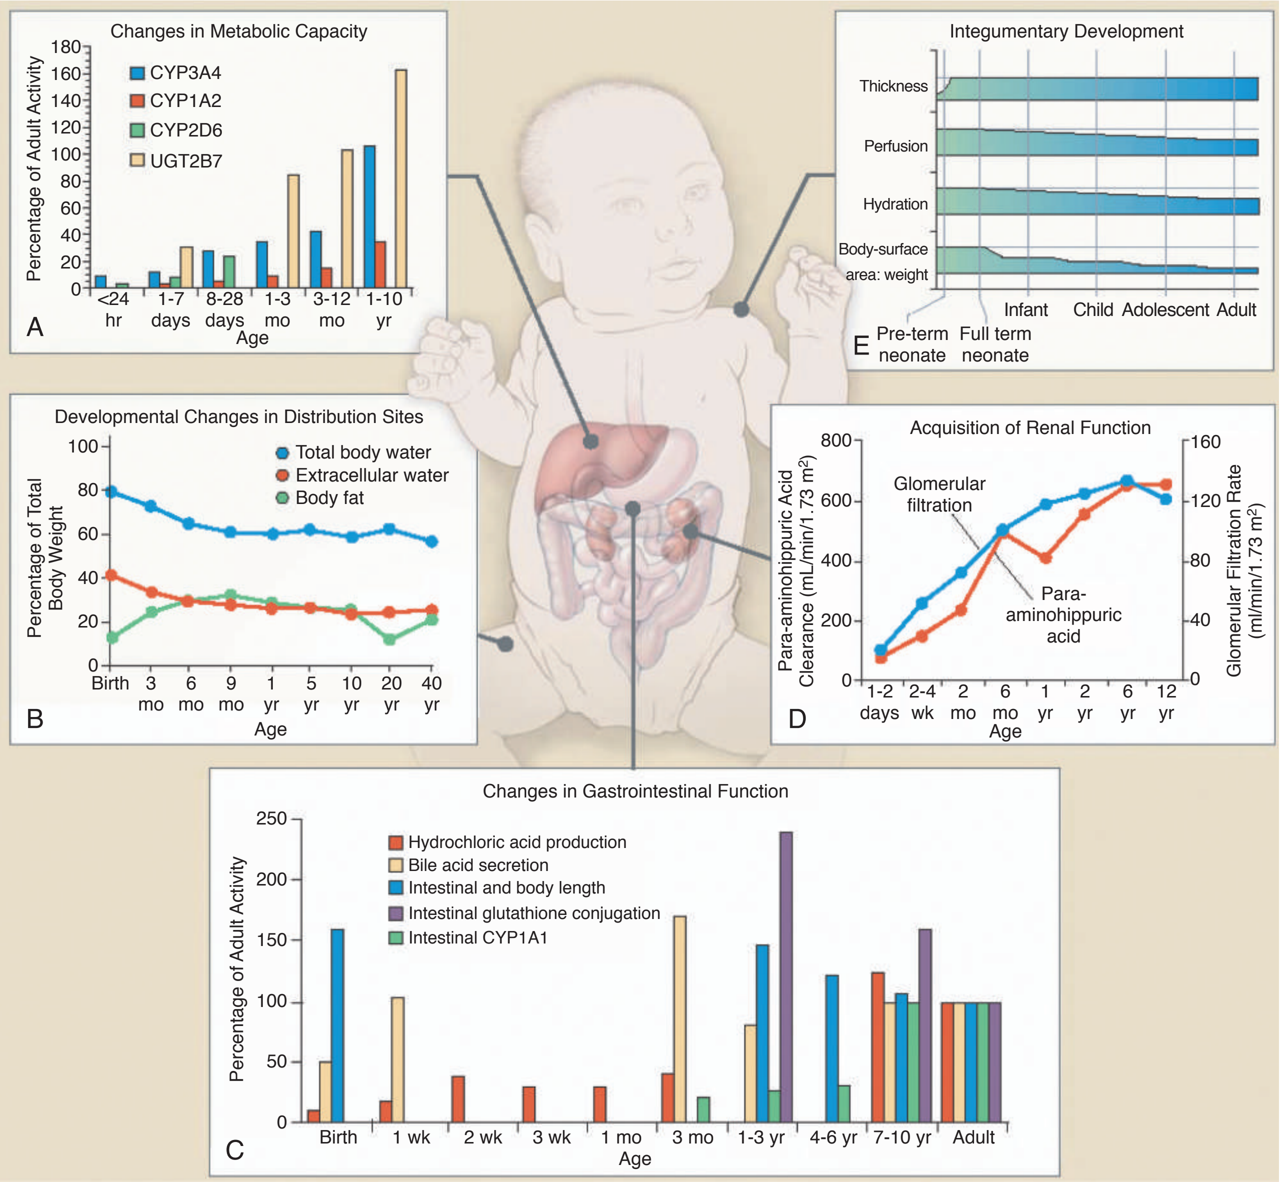

Figure 60-3 Developmental changes in physiologic factors that influence drug disposition in infants, children, and adolescents. Physiologic changes in multiple organ systems during development are responsible for age-related differences in drug disposition. **A**, As this graph shows, the activity of many cytochrome P450 (CYP) isoforms and a single glucuronosyltransferase (UGT) isoform is markedly diminished during the 1st 2 mo of life. In addition, the acquisition of adult activity over time is enzyme- and isoform-specific. **B,** This chart shows age-dependent changes in body composition that influence the apparent volume of distribution of drugs. Infants in the 1st 6 mo of life have markedly expanded total-body water and extracellular water, expressed as a percentage of total-body weight, as compared with older infants and adults. **C,** This graph summarizes the age-dependent changes in both the structure and function of the gastrointestinal tract. As with hepatic drug-metabolizing enzymes **(A)**, the activity of CYP1A1 in the intestine is low during early life. **D,** This chart shows the effect of postnatal development on the processes of active tubular secretion–represented by the clearance of paraaminohippuric acid and the glomerular filtration rate, both of which approximate adult activity by 6-12 mo of age. **E,** This graph shows age dependence in the thickness, extent of perfusion, and extent of hydration of the skin and the relative size of the skin-surface area (reflected by the ratio of body surface area to body weight). Although skin thickness is similar in infants and adults, the extent of perfusion and hydration diminishes from infancy to adulthood. *(From Kearns GL, Abdel-Rahman SM, Alander SW, et al, Developmental pharmacology—drug disposition, action, therapy in infants and children.* N Engl J Med *349:1157–1167, 2003. Reproduced with permission.)*

Gastric emptying time is prolonged throughout infancy and childhood consequent to reduced motility which may retard drug passage into the intestine where the majority of absorption takes place. Gastric emptying rates reach or exceed adult values by 6-8 mo of life. As such, intestinal motility is important for the rate of drug absorption and, like other factors, is dependent on the age of the child. Consequently, the rate of absorption of drugs with limited water solubility (e.g., phenytoin, carbamazepine) can be dramatically altered consequent to changes in gastrointestinal motility. In older infants and young children, more rapid rates of intestinal drug transit can reduce the bioavailability for some drugs (e.g., phenytoin) and/or drug formulations (e.g., sustained-release) by reducing their residency time at the absorption surfaces in the small intestine.

Lastly, neonates, particularly premature neonates, have a reduced bile acid pool and biliary function resulting in a decreased ability to solubilize and absorb lipophilic drugs. Even though biliary function

Table 60-1 Developmental Alteration in Intestinal Drug Absorption

PHYSIOLOGIC ALTERATION	NEONATE	INFANTS	CHILDREN
Gastric pH	>5	4-2	Normal (2-3)
Gastric emptying time	Irregular	Increased	Slightly increased
Intestinal motility	Reduced	Increased	Slightly increased
Intestinal surface area	Reduced	Near adult	Adult pattern
Microbial colonization	Reduced	Near adult	Adult pattern
Biliary function	Immature	Near adult	Adult pattern

Direction of alteration given relative to expected normal adult pattern.
Data from Morselli PL. Development of physiological variables important for drug kinetics. In: Morselli PL, Pippenger CE, Penry JK, editors. Antiepileptic drug therapy in pediatrics. *New York, 1983, Raven Press, pp. 1–12.*

develops in the 1st few months of life, it may be difficult for the neonate and young infant to absorb fat-soluble vitamins as low concentrations of bile acids are necessary for their absorption.

Extravascular Drug Absorption

With a bioavailability of 100%, intravenous drug administration is assumed to be the most dependable and accurate route for drug delivery. Absorption of drugs from tissues and organs (e.g., intramuscular, transdermal, and rectal) can also be affected by development (Table 60-2). Intramuscular blood flow changes with age, which can result in variable and unpredictable absorption. Reduced muscular blood flow in the 1st few days of life, the relative inefficiency of muscular contractions (useful in dispersing an IM drug dose), and an increased percentage of water per unit of muscle mass may delay the rate and/or extent of drugs given intramuscularly to the neonate. Muscular blood flow increases into infancy and, consequently, the bioavailability of drugs given by the IM route is comparable to that seen in children and adolescents.

In contrast, mucosal permeability (rectal and buccal) in the neonate is increased and thus, may result in enhanced absorption by this route. Transdermal drug absorption in the neonate and very young infant is increased as the result of a more hydrated stratum corneum (see Fig. 60-3*E*). In addition, the ratio of body surface area to body weight is greater in infants and children compared to adults. Collectively, these developmental differences may predispose the child to increased exposure and risk for toxicity for drugs/chemicals placed on the skin (e.g., silver sulfadiazine, topical corticosteroids, benzocaine, diphenhydramine) with higher likelihood of occurrence during the 1st 12 mo of life.

Normal developmental differences in drug absorption from most all extravascular routes of administration can influence the dose-plasma concentration relationship in a manner sufficient to alter pharmacodynamics. It should be recognized that the presence of disease states which influence a physiologic barrier for drug absorption and/or the time that a drug spends at a given site of absorption can further influence drug bioavailability and effect.

Drug Distribution

Drug distribution is influenced by a variety of drug-specific physiochemical factors (e.g., molecular size and weight, apparent partition coefficient, pK_a), the presence of drug transporters, blood/tissue protein binding, blood and tissue pH and perfusion. However, age-related changes to drug distribution are primarily related to developmental changes in body composition and the quantity of plasma proteins capable of drug binding. Age-dependent changes in the relative sizes of body water (total body water [TBW], extracellular water) and fat compartments may alter the apparent volume of distribution (VD) for a given drug. The absolute amounts and distribution of body water and fat depend on a child's age and nutritional status. As well, certain disease states (e.g., ascites, dehydration, burn injuries, disruption of the integument involving large surface area) can influence body water compartment sizes and thereby, further impact the VD for certain drugs.

Table 60-2 Influence of Ontogeny on Drug Absorption

PHYSIOLOGIC ALTERATION	NEONATE	INFANTS	CHILDREN
Oral absorption	Erratic	Increased	Near adult
Intramuscular absorption	Variable	Increased	Near adult
Percutaneous absorption	Increased	Increased	Near adult
Rectal absorption	Very efficient	Efficient	Near adult

Direction of alteration given relative to expected normal adult pattern.
Data from Morselli PL. Development of physiological variables important for drug kinetics. In: Morselli PL, Pippenger CE, Penry JK, editors. Antiepileptic drug therapy in pediatrics. *New York, 1983, Raven Press, pp. 1–12.*

Newborns have a much higher proportion of body mass in the form of water (~75% TBW) than older infants and children (see Fig. 60-3*B*). As well, the percent of extracellular water changes (decreases) from the newborn stage (approximately 45%) into adulthood (approximately 20-30%). In fact, the increase of TBW in the neonate is attributable to extracellular water. The reduction in TBW is rapid in the 1st year of life with adult values (approximately 55%) achieved by approximately 12 yr of age. In contrast, the percentage of intracellular water as a function of body mass remains stable from the 1st months of life through adulthood. The impact of developmental changes in body water spaces are exemplified by drugs such as the aminoglycoside antibiotics; compounds that distribute predominantly throughout the extracellular fluid space and have a higher VD (0.4-0.7 L/kg) in neonates and infants as compared to adults (0.2-0.3 L/kg).

Body fat percentage and composition increase during normal development. The body fat percentage in a neonate is approximately 16% (57% water and 35% lipid). Despite the relatively low body fat content in the neonate, it is important to note that the lipid content in the developing central nervous system (CNS) is high, which has implications for the distribution of lipophilic drugs and their CNS effects (e.g., propranolol) during this time period. The body fat percentage tends to increase up to approximately 10 yr of age and then changes composition with respect to puberty and sex to approach adult body fat composition (26% water and 71% lipid). In addition, a sex difference exists as the child ages into adolescence. The total body fat in males is reduced by 50% between 10 and 20 yr of life as compared to females in whom the reduction is approximately 25%.

Albumin, total proteins, and total globulins (e.g., α_1-acid glycoprotein) are the most important circulating proteins responsible for drug binding in plasma. The absolute concentration of these proteins is influenced by age, nutrition, and disease (Table 60-3). The concentrations of most all circulating plasma proteins are reduced in the neonate and young infant (approximately 80% of adult) and reach adult values by 1 year of age. A similar pattern of maturation is observed with α_1-acid glycoprotein (an acute-phase reactant capable of binding basic drugs) where neonatal plasma concentrations are approximately 3 times lower than in maternal plasma and attain adult values by approximately 1 year of age.

The extent of drug binding to proteins in the plasma may influence distribution characteristics. Only free, unbound drug can be distributed from the vascular space into other body fluids and, ultimately, to tissues where drug–receptor interaction occurs. Drug protein binding depends on a number of age-related variables, which can include the absolute amount of proteins and their available binding sites; the conformational structure of the binding protein (e.g., reduced binding of

Table 60-3 Factors Influencing Drug Binding in Pediatrics

PHYSIOLOGIC ALTERATION	NEONATE	INFANTS	CHILDREN
Plasma albumin	Reduced	Near adult	Near adult

PHYSIOLOGIC ALTERATION	NEONATE	INFANTS	CHILDREN
Cytochrome P450 activity	Reduced	Increased	Slightly increased
Phase II enzyme activity	Reduced	Increased	Near adult
Blood esterase activity	Reduced	Normal (by 1 yr)	Adult pattern
Presystemic enzyme activity	Reduced	Increased	Near adult

Direction of alteration given relative to expected normal adult pattern.
Data from Morselli PL. Development of physiological variables important for drug kinetics. In: Morselli PL, Pippenger CE, Penry JK, editors. Antiepileptic drug therapy in pediatrics. *New York, 1983, Raven Press, pp. 1–12.*

acidic drugs to glycated albumin in patients with poorly controlled diabetes mellitus); the affinity constant of the drug for the protein; the influence of pathophysiologic conditions that either reduce circulating protein concentrations (e.g., ascites, major burn injury, chronic malnutrition, hepatic failure) or alter their structure (e.g., diabetes, uremia); and the presence of either endogenous or exogenous substances, which may compete for protein binding.

Developmentally associated changes in drug binding can occur as a consequence of altered protein concentrations and/or binding affinity. For example, circulating fetal albumin in the neonate has significantly reduced binding affinity for acid drugs such as phenytoin, which is extensively (94-98%) bound to albumin in adults as compared to 80-85% in the neonate. The resultant 6-8–fold difference in the free fraction can result in CNS adverse effects in the neonate when total plasma phenytoin concentrations are within the generally accepted "therapeutic range" (10-20 mg/L). The importance of reduced drug-binding capacity of albumin in the neonate is exemplified by interactions between endogenous ligands (e.g., bilirubin, free fatty acids) and drugs with greater binding affinity (e.g., the ability of sulfonamides to produce kernicterus).

Drug transporters, such as P-glycoprotein, MDR1, and MDR2 (multidrug resistance 1 or 2), can influence drug distribution. These drug transporters can markedly influence the extent to which drugs cross membranes in the body and whether drugs can penetrate or are secreted from the target sites (inside cancer cells or microorganisms, or crossing the blood–brain barrier). Thus, drug resistance to cancer chemotherapy, antibiotics, or epilepsy may be conferred by these drug transport proteins and their effect on drug distribution. While there are limited data on the ontogeny of drug transport proteins, available information demonstrates their presence as early as 22 wk gestation and low levels in the neonatal period which appear to rapidly increase to adult values by 1-2 yr of age.

Drug Metabolism

Metabolism reflects the biotransformation of an endogenous or exogenous molecule by 1 or more enzymes to moieties that are more hydrophilic and thus, can be more easily eliminated by excretion, secretion or exhalation. Although metabolism of a drug generally reduces its ability to produce a pharmacologic action, it can result in metabolites that have significant potency, thereby contributing to the overall pharmacodynamic profile of a drug (e.g., biotransformation of the tricyclic antidepressant amitriptyline to nortriptyline; cefotaxime to desacetylcefotaxime; theophylline to caffeine) or in some instances, can produce significant toxicity (e.g., biotransformation of codeine to morphine). In the case of prodrugs (e.g., zidovudine, enalapril, fosphenytoin) or some drug salts/esters (e.g., cefuroxime axetil, clindamycin phosphate), biotransformation is required to produce a pharmacologically active moiety. Finally, for some drugs, cellular injury and associated adverse reactions are the result of drug metabolism (e.g., acetaminophen hepatotoxicity, Stevens-Johnson syndrome associated with sulfamethoxazole).

The primary organ responsible for drug metabolism is the liver, although the kidney, small intestine, lung, adrenals, blood (phosphatases, esterases) and skin can also biotransform certain compounds. Drug metabolism occurs primarily in the endoplasmic reticula of cells via 2 general classes of enzymatic processes: **phase I,** or nonsynthetic, and **phase II,** or synthetic, reactions. Phase I reactions include oxidation, reduction, hydrolysis, and hydroxylation reactions, whereas phase II reactions primarily involve conjugation with an endogenous ligand (e.g., glycine, glucuronide, glutathione or sulfate). As illustrated by Figure 60-3*A*, many drug metabolizing enzymes demonstrate an ontogenic profile with generally low activity present at birth and maturation over a period of months to years (Table 60-4).

Even though there are many enzymes that are capable of catalyzing the biotransformation of drugs and xenobiotics, the quantitatively most important are represented by the cytochromes P450 (CYPs), a supergene family with at least 16 primary enzymes. The specific CYP isoforms responsible for the majority of human drug metabolism are represented by CYP1A2, CYP2C9, CYP2C19, CYP2D6, CYP2E1, and CYP3A4. These enzymes represent the products of genes that in some instances, are polymorphically expressed with allelic variants producing enzymes generally resulting in either no or reduced catalytic activity (a notable exception being the *17 allele of CYP2C19 which conveys increased activity) (see Chapter 59). At birth, the concentration of drug-oxidizing enzymes in fetal liver (corrected for liver weight) appears similar to that in adult liver. However, the activity of these oxidizing enzyme systems is reduced, which results in slow clearance (and prolonged elimination) of many drugs that are substrates for them (e.g., phenytoin, caffeine, diazepam, and many others). Postnatally, the hepatic CYPs appear to mature at different rates. Within hours after birth, CYP2E1 activity increases rapidly with CYP2D6 being detectable soon thereafter. CYP2C (CYP2C9 and CYP2C19) and CYP3A4 are present within the 1st mo of life, and a few months later, CYP1A2. CYP3A4 activity in young infants may exceed that observed in adults as reflected by the clearance of drugs that are substrates for this enzyme (e.g., cyclosporine, tacrolimus).

Compared to phase I drug-metabolizing enzymes, the impact of development on the activity of phase II enzymes (acetylation, glucuronidation, sulfation) is not characterized as well. Generally speaking, phase II enzyme activity is decreased in the newborn and increases into childhood. For example, conjugation of compounds metabolized by isoforms of glucuronosyltransferase (UGT; e.g., morphine, bilirubin, and chloramphenicol) is reduced at birth but can exceed adult values by 3-4 yr of age. Also, the ontogeny of UGT expression is isoform specific. Newborns and infants primarily metabolize the commonly used analgesic acetaminophen by sulfate conjugation whereas the UGT isoforms responsible for its glucuronidation (UGT1A1 and UGT1A9) have markedly reduced activity. As children age, the

glucuronide conjugate becomes predominant in the metabolism of therapeutic doses of acetaminophen. In contrast, the glucuronidation of morphine (a UGT2B7 substrate) can be detected as early as 24 wk gestation.

The activity of certain hydrolytic enzymes, including blood esterases, is also reduced during the neonatal period. The reduced activity of these plasma esterases in the newborn may account for the delayed metabolism (prolonged effect) of local anesthetics in the neonate. In addition, this may account for the prolonged effect that cocaine has on the fetus with prenatal exposures. Adult esterase activity is achieved by 10-12 mo of age.

The development of presystemic clearance or "1st-pass" metabolism is unclear given the involvement of multiple enzymes and transporters in the small intestine, many of which have patterns of developmental expression that may be more or less concordant. However, given that the activity of almost all drug metabolizing enzymes is markedly reduced in the neonate, the bioavailability of drugs given by the peroral route that may be subjected to significant presystemic clearance in older children and adults would appear to be markedly increased during the 1st days to weeks of life. It is important for the clinician to recognize that estimates of bioavailability for a host of drugs available in reference texts and therapeutic compendia are most often derived from studies conducted in young adults. Consequently, this information may not be predictive of the rate and/or extent of peroral drug absorption in a neonate or infant.

Finally, with regard to the impact of development on drug metabolism, it must be recognized that most therapeutic drugs are polyfunctional substrates for a host of enzymes and/or transporters. It is the isoform specific ontogenic profile (see Fig. 60-3) that must be considered in the context of deducing how development per se can affect the metabolic portion of drug clearance. True developmental dependence of drug clearance (CL) must also consider the role of pharmacogenetic constitution on the activity of enzymes/transporters (see Chapter 59) and the impact of ontogeny on the nonmetabolic routes (e.g., renal drug excretion, salivary and biliary drug excretion, pulmonary drug excretion) that contribute to the overall drug clearance (i.e., Total CL = $CL_{hepatic} + CL_{renal} + CL_{nonrenal}$).

Renal Drug Elimination

The kidney is the primary organ responsible for the excretion of drugs and their metabolites. The development of renal function begins during early fetal development and is complete by early childhood (see Fig. 60-3*D*; Table 60-5). Total renal drug clearance *(CL_{renal})* can be conceptualized by considering the following equation:

$$CL_{renal} = (GFR + ATS) - ATR$$

where glomerular filtration rate *(GFR)*, active tubular secretion *(ATS)*, and active tubular reabsorption *(ATR)* of drugs can contribute to overall clearance. As is true for hepatic drug metabolism, only free (unbound) drug and/or metabolite can be filtered by a normal glomerulus and/or either secreted or reabsorbed via a renal tubular transport proteins.

Renal clearance is limited in the newborn by both anatomical and functional immaturity of the nephron unit. In both the term and preterm neonate, GFR averages 2-4 mL/min/1.73 m^2 at birth. During the 1st few days of life, a drop in renal vascular resistance occurs which results in a net increase in renal blood flow and a re-distribution of intrarenal blood flow from a predominantly medullary to a cortical distribution. All of these changes are associated with a commensurate increase in GFR. In term neonates, GFR increases rapidly over the 1st few months of life and approaches adult values by 10-12 mo of life (see Fig. 60-3*D*). The rate of GFR acquisition is blunted in preterm neonates consequent to continued nephrogenesis, which occurs in the early postnatal period. In young children between 2 and 5 yr of age, GFR may exceed adult values, especially during periods of increased metabolic demand (e.g., during a fever).

In addition, there is a relative glomerular/tubular imbalance because of a more advanced maturation of glomerular function. Such an imbalance may persist up to 6 mo of age and may account for the observed decrease in the ATS of drugs commonly used in neonates and young infants (e.g., β-lactam antibiotics). Finally, there is some evidence that ATR is reduced in neonates and that it appears to mature at a slower rate than the GFR.

Altered renal drug clearance in the newborn and infants result in the different dosing recommendations commonly seen in pediatrics. The aminoglycoside antibiotic gentamicin provides an illustrative example. In adolescents and young adults with normal values for GFR (85-130 mL/min/1.73 m^2), the recommended dosing interval for the drug is 8 hr. In young children who may have a GFR >130 mL/min/1.73 m^2, a gentamicin dosing interval of every 6 hr may be necessary in selected patients who have serious infections that require maintaining steady-state peak and trough plasma concentrations near the upper boundary of the recommended therapeutic range. In contrast, to maintain "therapeutic" gentamicin plasma concentrations in neonates during the 1st few weeks of life, a dosing interval of 18-24 hr is required.

The impact of developmental differences in GFR on the elimination characteristics of a given drug can be assessed by estimating the apparent elimination rate constant (Kel) for a drug by using the following equation:

$$\text{Kel (in reduced renal function)} = Kel_{normal} \cdot \{[(GFR_{observed}/GFR_{normal}) - 1] \cdot Fel\} + 1$$

where the *Fel* represents the fraction of the drug excreted unchanged in an adult with normal renal function, $GFR_{observed}$ is the value calculated (from creatinine clearance or an age-appropriate estimation equation) for the patient (in mL/min/1.73 m^2), GFR_{normal} is the average value considered for a healthy adult (i.e., 120 mL/min/1.73 m^2) and Kel_{normal} is estimated from the average elimination $T_{1/2}$ (terminal half-life) for a drug taken from the medical literature using the following equation:

$$Kel_{normal}\,[hr^{-1}] = 0.693/T_{1/2 normal}\,[hr]$$

Table 60-5 Impact of Development on Renal Drug Elimination

PHYSIOLOGIC ALTERATION	NEONATE	INFANTS	CHILDREN
Glomerular filtration	Reduced	Normal (by 1 year)	Adult pattern
Active tubular secretion	Reduced	Near normal	Adult pattern
Active tubular reabsorption	Reduced	Near normal	Adult pattern
Active drug excretion	Reduced	Near normal	Adult pattern
Passive drug excretion	Reduced	Increased	Adult pattern
Excretion of basic drugs	Increased	Increased	Near normal

Direction of alteration given relative to expected normal adult pattern.

Data from Morselli PL. Development of physiological variables important for drug kinetics. In: Morselli PL, Pippenger CE, Penry JK, editors. Antiepileptic drug therapy in pediatrics. *New York, 1983, Raven Press, pp. 1–12.*

Likewise, the elimination $T_{1/2}$ for a drug in patients with reduced renal function can be estimated as follows:

$T_{1/2}$ (in reduced renal function) = 0.693/Kel (in reduced function)

An estimate of the drug elimination $T_{1/2}$ in patients with reduced renal function with knowledge of the desired interdose excursion in steady-state plasma concentrations can provide an ability to determine the desired drug dosing interval.

Impact of Ontogeny on Pharmacodynamics

Although, it is generally accepted that developmental differences in drug action exist, there is little evidence of true age-related pharmacodynamic variation among children of differing age groups and adults. Drug action is typically mediated by interaction of a small molecule with 1 or more receptors, which may be located either on or in a cell. Drug effect is mediated at the receptor by 4 main biochemical mechanisms involved in cell signaling. Binding of the receptors on the cell surface or within the cell activate downstream pathways that mediate a specific cellular action. Some receptors act as enzymes whereby, upon ligand binding, the enzyme phosphorylates downstream effector proteins, thereby activating or inhibiting a cellular signal. Guanosine triphosphate–binding regulatory protein, also known as G-protein–coupled receptors, are known targets for many drugs. Upon ligand binding, guanosine triphosphate binds to and activates the G-protein, in turn allowing it to activate second messenger regulatory proteins in the cell, again mediating cellular signaling. Other receptors mediate their actions through ion channels whereby, upon ligand binding, the cell's membrane potential or ionic composition is altered allowing cellular activation or inhibition. Lastly, some receptors act as transcription factors that, when bound by a ligand, transcription of specific genes within the cell are activated. Drug action is concentration dependent with onset and offset generally associated with appearance and disappearance, respectively, of the drug at the receptor(s) in an amount that is sufficient to initiate the cascade of biologic effects that terminate in drug action (see Fig. 60-1). The minimum effective concentration of a drug is that observed with the immediate onset of effect, whereas the duration of action is predicated upon the maintenance of drug concentrations at the receptor within a range that is associated with the desirable pharmacologic action(s). Receptor binding by a drug may have varying consequences. Drugs that are **agonists** bind to and activate the receptor, directly or indirectly achieving the desired effect. An agonist binding to a receptor results in the same biologic effect as binding of the endogenous ligand. **Partial agonist** binding results in activation of the receptor but maximal effect is not achieved even in the presence of receptor saturation. **Antagonists** bind to a receptor preventing binding of other molecules thereby preventing activation of the receptor.

Age-related pharmacokinetic variation resulting in altered drug disposition may result in less or more drug being available at the receptor(s) consequent to whether drug clearance is decreased or increased relative to values in adults. The resultant alteration in the dose–concentration profile may result in an attenuated (ineffective) or exaggerated (toxicity) response in children, which is especially relevant for drugs with a narrow therapeutic index (Fig. 60-4). Thus, in some circumstances, apparent developmental differences in drug response/effect may be simply explained on pharmacokinetic basis.

There is evidence supporting developmental differences in receptor number, density, distribution, function, and ligand affinity for some drugs. As there are limited data from humans, much of what is known has been derived from animal studies. In the CNS, unique developmental aspects of drug–receptor interaction affect therapeutic efficacy of both analgesic and sedative drugs in neonates. For example, the number of γ-aminobutyric acid receptors, which mediates inhibitory signal transduction in the CNS, is reduced in newborns compared to adults. Functional differences have also been observed between neonatal and adult brain upon γ-aminobutyric acid receptor activation. These changes may explain observed differences in dosing of drugs such as midazolam in infants, and in part may explain seizures experienced by infants upon benzodiazepine exposure. Another example

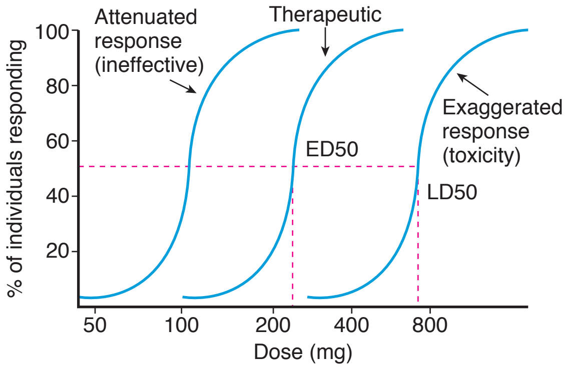

Figure 60-4 **Quantal dose–effect curve.** Age-related pharmacokinetic variation may result in alterations in drug concentration at the receptor resulting in ineffective, therapeutic, or toxic results. LD_{50} represents the dose at which 50% of the population is lethal. The ratio of the LD_{50} to the ED_{50} is an indication of the therapeutic index, which is a reflection of drug potency relative to its concentration.

in the CNS is illustrated by the μ-opioid receptor whereby receptor number is reduced in newborns and receptor distribution also differs between newborns and adults.

For the clinician, the consideration of age-dependent differences in pharmacodynamics is particularly relevant when they are associated with adverse drug reactions (e.g., higher incidence of valproic acid-associated hepatotoxicity in young infants; greater frequency of paradoxical CNS reactions to diphenhydramine in infants; weight gain associated with use of atypical antipsychotic drugs in adolescents) or when drugs have a narrow therapeutic index. This latter situation is exemplified by the immunomodulatory agent cyclosporine and the anticoagulant warfarin. In children younger than 1 yr old, the mean concentration of cyclosporine required to inhibit monocyte proliferation and the expression of the inflammatory cytokine interleukin-2 is less than required in older children. The age-associated pharmacodynamics of warfarin observed in children with congenital heart disease is, to a great degree, associated with developmental differences in serum concentrations of vitamin-K dependent coagulation factors (II, VII, IX, X) between children and adults. Developmental differences in drug action have also been observed between prepubertal children and adults with regard to warfarin action. Prepubertal children compared to adults exhibit a more profound response, demonstrated by lower protein C concentration, prothrombin fragments 1 and 2, and greater rise in international normalized ratio, to comparable doses of warfarin. Thus, when age-dependent pharmacodynamics of a given drug are evident, the use of simple allometric approaches for "scaling" the pediatric dose from the usual adult dose may not produce the desired pharmacologic effects.

Surrogate End Points

The assessment of pharmacodynamics in human infants and children has been hampered historically by a relative inability to use invasive methods for the direct assessment of drug effect. As a result, surrogate end points and biomarkers have been explored and, in some cases, have been successfully used to evaluate the impact of ontogeny on pharmacodynamics.

Biomarkers and surrogate end points (markers) are ideally simple, reliable, inexpensive, and easily obtainable measures of a biologic response or disease phenotype that can be used to facilitate either clinical research or patient care. **Biomarkers** have been defined by the U.S. National Institutes of Health as "a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention." A **surrogate end point** is defined "as a biomarker that is intended to substitute for a specific clinical end point. A surrogate end point is expected to predict clinical benefit (or harm or lack of benefit or harm) based on epidemiologic, therapeutic, pathophysiologic, or

other scientific evidence." Reliable surrogate end points predict a specific physiologic event(s) (e.g., intraesophageal pH to assess gastroesophageal reflux), which may be utilized diagnostically, prognostically, or in predicting a specific drug response (therapeutic, subtherapeutic, or adverse) or potentially, the impact of ontogeny on pharmacodynamics. Specific examples of surrogate end points used in pediatric pharmacology include measurement of esophageal pH to assess the action of prokinetic or acid-modifying drugs, use of gastric scintigraphy and stable isotope-labeled compounds (e.g., ^{13}C-acetate, ^{13}C-octanoic acid) to assess gastric emptying rate, and pulmonary function tests (e.g., forced expiratory volume at 1 sec) to evaluate the effect(s) of drugs on pulmonary function in patients with conditions such as asthma and cystic fibrosis. Examples of biomarkers that have been used in pediatric studies to assess drug disposition or effect include hemoglobin A_{1C} plasma concentration (to assess efficacy of peroral hypoglycemic agents); urinary leukotriene concentrations (to assess effects of nonsteroidal antiinflammatory drugs); minimal inhibitory and minimal bacteriocidal concentrations of drugs to selected antiinfective agents; and the use of selective genotyping tests (e.g., projection of therapeutic warfarin dose requirement by use of *CYP2C9* [gene controlling expression of the enzyme primarily responsible for warfarin metabolism] and *VKORC1* [gene controlling expression of enzyme primarily involved in regulating warfarin effects on vitamin K dependent clotting factors] genotyping.

Additional Considerations in Pediatric Therapeutics

The use of adult-dose modification for pediatric dose prediction is based on the association between body size/composition and the physiologic determinants of drug disposition across the spectrum of age. Although these approaches may have some potential clinical utility in children older than 8 yr of age and in adolescents whose organ function and body composition approximates that of young adults, their utility is severely limited in neonates, infants, and children younger than 2 yr of age in whom ontogeny produces dramatic differences in drug disposition. This is especially problematic for therapeutic drugs whose doses cannot be easily individualized using patient-specific pharmacokinetic data obtained from therapeutic drug monitoring.

More than 20 different approaches for initial selection of a drug dose for pediatric patients have been described. The majority of these utilize either total body weight (BW) or body surface area (BSA) as surrogates, which reflect the developmental changes of either body composition or organ function that collectively are the major determinants of drug disposition. Dose selection based on BW or BSA will generally produce similar relationships between drug dose and resultant plasma concentration, except for those drugs whose apparent VD corresponds to the extracellular fluid pool (i.e., VD < 0.3 L/kg) for which a BSA-based approach is preferable. In contrast, for drugs whose apparent VD exceeds the extracellular fluid space (i.e., VD ≥ 0.3 L/kg), a BW-based approach for dose selection is preferable, which is the most frequently used method in pediatrics. When the pediatric dose for a given drug is not known, these principles can be used to best approximate a proper dose for the initiation of treatment as is illustrated by the following equations:

$$\text{Child dose (if VD} < 0.3\text{ L/kg)} = (\text{child BSA in m}^2/1.73\text{ m}^2) * \text{adult dose}$$

$$\text{Infant dose (if VD} \geq 0.3\text{ L/kg)} = (\text{infant BW in kg}/70\text{ kg}) * \text{adult dose}$$

It should be noted that this approach assumes that the child's weight, height, and body composition are age appropriate and normal, and that the "reference" normal adult has a BW and BSA of 70 kg and 1.73 m^2, respectively. It is useful only for selection of dose size and does not offer information regarding dosing interval because the equations contain no specific variable that describes potential age-associated differences in drug clearance.

In neonates and young infants with developmental immaturity in either GFR and/or ATS, it is often necessary to adjust the "normal" dosing interval (i.e., that used for older infants and children who have attained developmental competence of renal function) for drugs with significant (i.e., >50%) renal elimination so as to prevent excessive drug accumulation (and possible associated toxicity) with administration of multiple doses. To accomplish this therapeutic goal, it is necessary to estimate the apparent $T_{1/2}$ of the drug.

Drug-Level Monitoring

Drug response (either therapeutic or toxic) occurs only as a consequence of drug exposure. Clinically, systemic drug exposure is most commonly evaluated through assessing the plasma drug concentration; a surrogate measurement for a drug reaching its pharmacologic receptor(s).

In the patient, drug-level monitoring can be used to facilitate 2 approaches for evaluating the dose–concentration–effect relationship; therapeutic drug monitoring and pharmacokinetic-based dose individualization (clinical pharmacokinetics). **Therapeutic drug monitoring** largely entails a retrospective, reactive approach whereby drug concentrations in plasma (primarily) or other biologic fluids are measured at some point during either a constant rate intravenous infusion or during a dosing interval for drugs given by intermittent dosing schedules. These levels are then compared with those that are "desired" for a given drug based on published information and used to adjust the dose/dosing regimen in a quasi-empiric fashion. In using a therapeutic drug-monitoring approach, it should be recognized that for many drugs that are therapeutically monitored in the clinical setting (e.g., aminoglycoside antibiotics, vancomycin, phenytoin, phenobarbital, cyclosporine, tacrolimus, mycophenolate mofetil, selected antiretroviral drugs, acyclovir), "desired" plasma concentrations are generally determined from studies in adult patients in whom drug disposition and disease states may be quite different from those in infants and children.

In contrast to therapeutic drug monitoring, **clinical pharmacokinetics** represents a prospective, proactive approach where plasma drug concentrations are used to estimate pharmacokinetic parameters (e.g., apparent Kel, elimination $T_{1/2}$, apparent VD, total plasma clearance, AUC) which are then used to calculate a dosing regimen required to attain a desired level of systemic exposure (e.g., AUC, steady-state peak and/or trough plasma drug concentrations) that would portend a desired pharmacologic response. Of these 2 approaches, the use of drug-level data for performing clinical pharmacokinetics provides the most optimal approach for individualizing dose/dosing regimen and maintaining some adaptive control over the dose-concentration- effect relationship. This approach is particularly useful for patients who by virtue of their age and/or disease states, may have "abnormal" pharmacokinetics. Approaches used to enable the performance of clinical pharmacokinetics include the manual use of established formulas for calculating pharmacokinetic parameters (generally using a simple 1 compartment open model consequent to the few number of plasma drug-level observations obtained in the context of clinical patient care) or computer-based algorithms (e.g., Bayesian estimation, population-based pharmacokinetic approaches).

Common to both of the aforementioned approaches is the need to accurately assess plasma drug concentrations in a given patient. Figure 60-5 represents a hypothetical general steady-state plasma concentration vs time profile for a drug given by an extravascular route. It is provided to illustrate the following general principles that should be recognized and/or followed when plasma drug-level monitoring is used in patients as a "tool" to individualize drug treatment:

- When a drug reaches a pharmacokinetic steady state (a period corresponding to 5 times the apparent elimination $T_{1/2}$ for a given drug), both the excursion between the peak (C_{max}) and trough (C_{min}) plasma concentration and the AUC are identical between dose intervals provided that (1) the dose is not changed; (2) an exact dose-to-dose interval is maintained for drug administration; and (3) the route or rate of drug administration between dosing intervals has not changed.
- Steady-state plasma drug concentrations provide the best surrogate for assessing exposure–response relationships for a given drug. When used to support clinical pharmacokinetic approaches for dose regimen design, they provide the most accurate estimation of patient-specific pharmacokinetic parameters. Plasma

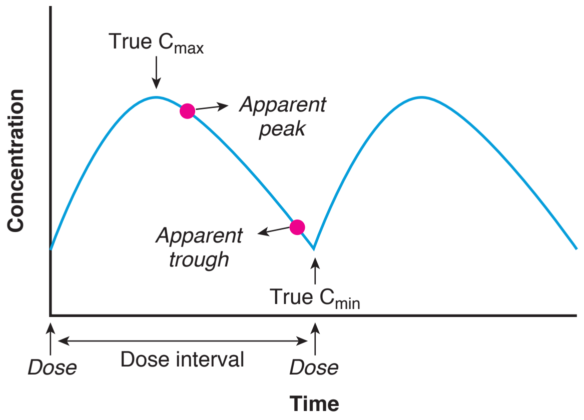

Figure 60-5 **Plasma concentration vs time profile for a hypothetical drug at steady state.** When dose size, route of administration, time of administration, and dosing interval remain constant, the resultant true peak (C_{max}) and trough (C_{min}) plasma concentrations and AUC from dose to dose are identical. Apparent values for C_{max} and C_{min} are denoted to illustrate the potential difference from true values that can result when the actual times for obtaining samples for either therapeutic drug monitoring or clinical pharmacokinetic applications are not realized.

concentrations assessed before the attainment of steady state can be useful for evaluating exaggerated drug response or predicting eventual steady-state drug levels/exposure.

To reliably interpret any drug plasma concentration, it is imperative that the clinician know and consider (1) the expected pharmacokinetic profile for a given drug (e.g., time after dosing required for completion of drug absorption (for extravascularly administered drugs) and distribution); (2) the exact time that the drug was administered; (3) for drugs given by intravenous infusion, the total duration of infusion (including time required to flush the dose from the intravenous tubing); (4) pertinent limitations of the analytical method used to measure the plasma drug level (e.g., range of linearity, potential for analytical interference from concomitant drugs); (5) the method used to obtain the blood specimen(s) used for plasma level determination (e.g., venous puncture vs cutaneous puncture; use of a vascular catheter that was different from the catheter used for drug administration); (6) whether the blood specimen was adequate for accurate drug level measurement (e.g., sufficient volume, presence or absence of hemolysis or lipemia); and (7) the *exact* time that the blood specimens were obtained in relationship to the time of drug administration and the drug dosing interval. This last point is illustrated by Figure 60-5, which denotes the "true" peak (C_{max}) and trough (C_{min}) plasma concentrations in relationship to apparent values; a situation that frequently occurs when "peak" and "trough" blood levels are ordered and nursing/phlebotomy procedures allow some period of leeway as to when they can be obtained. When such a discrepancy is realized and the exact timing of the samples relative to dose administration is known, corrections can be made to insure that pharmacokinetic parameters estimated from the data are accurate. If such a discrepancy is not realized, errant parameter estimation and dose regimen calculation/determination may result, thereby compromising either the safety or efficacy of drug treatment.

Drug Formulation and Administration

One of the more unique challenges in pediatric therapeutics is the **drug formulation** itself. Despite the increasing sensitivity for the need to study drugs in children before they are used in children and to have available "pediatric-friendly" formulations, many drug products that are formulated only for use in adults are routinely given to pediatric patients. Their use can result in inaccurate dosing (e.g., administration of a fixed dose to children with widely varying body weights), loss of desired performance characteristics of the formulation (e.g., crushing a sustained-release tablet or cutting a transdermal patch) and the exposure of infants and children to excipients (e.g., binding agents, preservatives) in amounts capable of producing adverse effects.

Peroral Drug Administration

One of the principal determinants of peroral drug administration in children is the ability to actually get the drug into the body. Peroral formulations are often expelled by children because of poor taste and texture. This is a significant issue, especially when considering that taste sensation differs as a consequence of development and on an interindividual basis. Solid formulations, such as tablets and capsules, are not easily administered to the majority of infants and children owing to their inability to easily and safely swallow them. For example, incomplete development of swallowing coordination may result in choking or aspiration when solid formulations are given to infants and small children. Finally, solid peroral formulations limit the ability for dose titration and dosing flexibility. Drug developers in the United States and abroad are working to address this limitation by the development of new techniques suitable for both oral and peroral drug administration that encompass both products (e.g., dispersible peroral tablets, oral films, titratable granules, oral melts) and drug administration devices (e.g., dosing straws, graduated cylinders for peroral granules).

With regard to dosing accuracy with peroral formulations, liquids (e.g., drops, solutions, syrups, suspensions, elixirs) are preferred for infants and young children. The utility of these formulations is often limited by palatability when taste-masking of the active ingredient(s) cannot be effectively achieved. In the case of suspension formulations, improper reconstitution and/or resuspension prior to dose administration can introduce problems related to accuracy of dosing. Other potential limitations of peroral liquid drug formulations (including those that may be extemporaneously compounded by the pharmacist from drug powder or from solid peroral dosage forms of a given drug) include potential problems related to drug stability, contamination (chemical or bacterial), portability and for some products, the need for them to be refrigerated so as to insure drug stability.

Administration of liquid medications can be associated with risk if the device for administering the medication is not appropriate (e.g., use of a kitchen teaspoon as opposed to a 5.0 mL dosing spoon) or used improperly when measuring a dose that is appropriate for the patient's age or weight. The low cost and convenience of hypodermic syringes has prompted many physicians and pharmacists to dispense them with liquid medications in order to improve accuracy. Although this approach is seemingly associated with greater accuracy in dosing, parents/caregivers can have difficulty in reading the graduations on a syringe and, also, the plastic caps on the plungers of syringes can produce a choking hazard for infants and young children. All of these problems can be obviated by education of parents/caregivers on how to reliably use special syringes for peroral dosing that pharmacists should dispense with every liquid drug formulation.

Parenteral Drug Administration

In contrast to adults where vascular access is relatively easy to obtain, difficulties are often present in the infant and young child. These are often produced by the smaller diameter of peripheral vessels (relative to the size of the intravenous cannula), developmentally associated differences in body composition (e.g., body fat distribution) and the use of topical anesthetic agents, some of which can produce venous constriction. The small peripheral blood vessels in infants and young children can also limit the volume and rate of intravenous drug administration because of issues of capacity and, in the instance of drugs capable of producing venous irritation, infusion-related discomfort.

An underappreciated issue that can complicate parenteral drug administration to infants occurs when the concentration of a given drug formulation does not enable accurate measurement of dose. Errors consequent to improper dilution of adult formulations necessary to ensure appropriate osmolarity and volume for IV administration (the most common resulting in a 10-fold overdose) are not uncommon. For example, morphine, a drug commonly used in neonates, infants, and children, is commonly available in a 2 mg/mL

concentration. A usual 0.1 mg/kg morphine dose for a 1 kg infant using this formulation would require a nurse or pharmacist to accurately withdraw 0.05 mL and administer it into a length of IV tubing with a dead space volume that may exceed that of the dose by approximately 100-fold. In this situation, accuracy of dose and infusion time can be significantly compromised. Although underdosing is often a serious problem when attempting to administer very small volumes, overdoses also occur, owing to inaccurate extemporaneous dilutions. Moreover, attempts to compensate for the volumes present within the IV tubing further predispose the patient to receive an incorrect, possibly unsafe, dose. Whenever such concentrated drug formulations are the only source for use, appropriate alteration of the stock parenteral solution should be performed and manufactured by the pharmacy department. As well, many errors can be avoided by the use of standard dilutions that all practitioners are aware of and using standardized approaches for IV drug administration that minimize complications associated with unrealized drug dilution and errant infusion times (e.g., pediatric syringe pumps attached to low-volume tubing).

Although used rather infrequently, IM drug administration offers a route of administration for many drugs in those instances where venous access is not immediately available or when a therapeutic drug regimen involves use of a single or limited number of doses. Although appealing with respect to immediacy, this route of administration can be associated with problems (e.g., muscle and/or nerve damage, sterile abscess formation, variable rate of drug absorption consequent to developmental differences in vascular perfusion of muscle beds), especially in the neonate and small infant. Finally, the decision to utilize the IM route must take into consideration the physicochemical properties (e.g., pH, osmolarity, solubility) of the drug formulation and/or any diluent used to prepare it.

Other Routes for Drug Administration

Neonates, infants, children, and adolescents with certain pulmonary conditions (e.g., reactive airway disease, viral-induced bronchiolitis, asthma, cystic fibrosis) frequently receive drugs (e.g., corticosteroids, β-adrenergic agonists, antimicrobial agents, mucolytic drugs) via inhalation. The pulmonary surface area in pediatric patients of all ages is a very effective, easily traversable barrier for drug absorption. Rate-limiting factors for pulmonary drug absorption include physicochemical factors associated with the drug and delivery system (e.g., particle size, diffusion coefficient, chemical stability of drug molecule in the lung) and physical factors that influence intrapulmonary drug deposition (e.g., active vs passive drug delivery to the tracheobronchial tree, respiratory minute volume, internal airway diameter); many of which are developmentally determined. For drugs formulated for delivery using a metered-dose inhaler (either drug powder or suspended particles using a carrier gas), developmental factors (e.g., incoordination of device actuation with inhalation, inability to follow instructions for clearing of airway, and passive inhalation with actuation of delivery device) either prevent their use (such as in infants and small children) or limit the bioavailability of the drug to be administered. In these instances, specific devices (e.g., masks, spacer chambers) and/or methods of delivery (e.g., continuous aerosolization via mask) can be used to improve the efficiency of drug delivery and, thereby, drug efficacy.

In pediatric patients, percutaneous drug administration is generally reserved for agents intended to produce a local effect within the dermis. Development has an impact on the barrier of the skin that, if not recognized and controlled for, can produce situations in which systemic toxicity can result (see "Drug Absorption" above). Similar therapeutic challenges occur when transmucosal routes (e.g., buccal, sublingual, rectal) are used for drug administration. Specifically, unpredictable systemic bioavailability may complicate treatment consequent to variability in the rate and/or extent of drug absorption. Finally, direct intraosseous drug administration via puncture of the tibia is occasionally used in infants and small children for administration of drugs and crystalloid fluids given acutely during resuscitation efforts. It is particularly useful when vascular access sufficient for drug administration cannot be immediately accomplished as the onset of action by this route is comparable with that seen after IV administration.

Adherence and Compliance

Beyond proper individualization of drug dose based on developmental considerations, the influence of concomitant disease/treatment and the selection of the proper drug formulation, the success of drug treatment in a pediatric patient is inextricably linked to the successful administration of the drug. Physical and cognitive immaturity makes the infant and the child a dependent creature in almost all respects, including those related to therapeutic drug administration. Until a child reaches an age at which they can physically self-administer a drug in an accurate, proficient fashion and can mentally assume responsibility for this task (generally from 7-14 yr of age, depending on the individual child), compliance with a drug regimen becomes the responsibility of an adult. In a hospital environment, compliance is ensured through the actions of physicians, nurses, and pharmacists who, collectively through an integrated system of medical care, assume this responsibility. Upon discharge, the responsibility is transferred to parents/guardians or other adult caregivers in an environment that is generally nonmedical. At this juncture, therapeutic compliance morphs into adherence as defined by the potential for conflicting demands (e.g., multiple adult caregivers; different external environments such as home, daycare, school; parents tending to the needs of multiple children) to introduce variability (anticipated and unpredictable) in drug administration. Whether treatment is for a self-limiting (e.g., antibiotic administration) or chronic (e.g., asthma, diabetes) condition, challenges to therapeutic adherence have the potential to serve as primary determinants of drug safety and efficacy in infants and young children.

In contrast to the period encompassing infancy and childhood, adolescence poses its own unique challenges to therapeutic adherence. During this period, psychosocial maturation almost always lags behind physical maturation. Development of cognitive and physical skills in most adolescents enables them to self-administer a prescribed medication in a proper manner with little to no supervision. However, psychodynamic issues experienced by a substantial number of adolescents (e.g., complete understanding of the ramifications of undertreatment, disease progression, and/or roles of disease prevention, and/or health maintenance; perceptions of immortality and the associated lack of need for treatment; disorganized patterns of thinking capable of confounding treatment schedules; defiant/oppositional behavior toward authority figures) can often precipitate therapeutic failure, through either undertreatment or overtreatment, the latter occasionally leading to drug toxicity. Unfortunately, the only maneuver that can be used to facilitate therapeutic compliance and adherence in the pediatric patient is the combination of vigilance (on behalf of all caregivers) and repetitive education coupled with positive reinforcement (e.g., the use of motivational interviewing techniques). When children reach the age of assent (i.e., generally by 7 yr of age in children who have normal neurobehavioral development), they have the beginning level of cognitive ability sufficient to engender understanding about their medical condition(s) and how effective treatment can be used to improve their life. Through diligent efforts placed toward patient education and reeducation, older children and adolescents can assume a level of responsibility for active partnership in their overall medical management, one that will mature as educational efforts, driven by a shared desire for an optimal outcome, are regularly made. The pediatrician's role in fostering this is paramount given their understanding of development and the regular patient–parent interactions that occur from birth through adolescence.

Drug–Drug Interactions

Pharmacokinetic and/or pharmacodynamic properties of drugs may be altered when 2 or more drugs are coadministered to a patient (refer to Table 60-6). Even though many interactions occur at the level of drug metabolism, they may also occur at the level of drug absorption (e.g., inhibition of intestinal CYP3A4 activity by grapefruit juice or St. John's wort and consequent reduction in presystemic clearance of

Table 60-6 Mechanism-Based Drug Interaction Table

PHARMACODYNAMIC	EXAMPLE DRUG COMBINATION	RESULT
Additive	a. Fentanyl and midazolam b. Class 1A antiarrhythmic with erythromycin c. Vancomycin plus aminoglycoside	Use of multiple medications with similar side effect profiles can lead to additive effects such as increased sedation (a), increased QT prolongation (b), and increased potential for nephrotoxicity (c)
Synergy	Penicillin plus aminoglycoside	Improved bactericidal efficacy against some Gram-positive organisms. Use of penicillin inhibits bacterial cell wall synthesis which for some Gram-positive organisms can improve the intracellular penetration of the aminoglycoside, which inhibits bacterial cell protein synthesis by binding to 30S and 50S ribosomal subunits
Antagonism	Opiate plus naloxone	Competitive receptor antagonism: Decreased efficacy of opiate medications, improvement in respiratory effort
PHARMACOKINETIC		
Absorption	*Inhibition of MDR1:* Amiodarone and digoxin	Increased digoxin concentration, digoxin toxicity (↓ digoxin 50%)
	Complex formation: Quinolone and tetracycline antibiotics with divalent/trivalent cations (e.g.; Ca^{2+}, Mg^{2+}, Fe^{3+}, Al^{3+})	Decreased antibiotic absorption
	Mycophenolate mofetil plus antacids	Decreased absorption of mycophenolate mofetil
	Pharmaceutical preparations: Ceftriaxone with IV fluids containing calcium	Crystalline deposits in lungs/kidneys of neonates
Distribution	Ceftriaxone + endogenous bilirubin	Displacement of bilirubin from albumin binding site, increased risk kernicterus in neonates
	NSAID plus warfarin	Displacement of warfarin from albumin binding site with consequent exaggerated anticoagulant response
Metabolism	*Induction:* Rifampin plus antiretrovirals	Decreased serum concentration of antiretroviral because of induced CYP metabolism
	Inhibition: Azole antifungals plus CYP3A4 substrates	↑ Drug levels because of inhibition of CYP3A4-mediated metabolism resulting in drug toxicity
Elimination	Penicillin plus probenecid	Decreased tubular secretion of penicillin resulting in increased serum concentrations
	Methotrexate plus aspirin	Inhibition of renal tubular secretion of methotrexate resulting increased methotrexate concentration

This table is not meant to be an all-inclusive list of drug–drug interactions. Care should be taken when prescribing all medications, and the potential of interactions should be considered. The practitioner is encouraged to assess the possibility of all interactions when prescribing medications.

NSAID, nonsteroidal antiinflammatory drug.

Modified from Rizack M, Hillman C: The Medical Letter handbook of adverse drug interactions. *New Rochelle, NY, 1989, The Medical Letter.*

CYP3A4 substrates), distribution (e.g., displacement of warfarin plasma protein binding by ibuprofen with consequent increased hemorrhagic risk), or elimination (e.g., inhibition of ATS of β-lactam antibiotics by probenecid). Drug–drug interactions may also occur at the level of the receptor (via competitive antagonism), many of which are intentional and produce therapeutic benefit in pediatric patients (e.g., antihistamine reversal of histamine effects, naloxone reversal of opiate adverse effects).

Drug–drug interactions that occur at the level of drug metabolism can be somewhat predictable based on a priori knowledge of a given drug's biotransformation profile. Although such information can be derived from the primary literature, it may not be immediately translated into a useful clinical context consequent to limitations associated with in vitro to in vivo extrapolation, which can include (1) use of animal models for characterizing metabolism; (2) extrapolating enzyme kinetics derived from pooled human liver microsomes or recombinant human drug-metabolizing enzymes to estimates of in vivo drug clearance; (3) extrapolating in vitro data obtained from fully competent (i.e., adult activity) hepatic microsomes to estimates of clearance in patients who may have developmental and/or disease-associated compromise in enzyme activity; (4) inaccurate accounting for pharmacogenetic variation in drug-metabolizing activity (i.e., constitutive activity); (5) the contribution of multiple different drug-metabolizing enzymes in the overall biotransformation of a given drug (i.e., a polyfunctional drug substrate); and (6) the potential role of enzyme induction or inhibition in vivo that is not reflected from conditions used for in vitro metabolism studies.

Despite these limitations, information pertaining to drug–substrate interaction can be useful in ascertaining the direction (e.g., enzyme inhibition → reduced clearance → higher plasma drug concentration → enhanced effect as compared to enzyme induction → increased clearance → reduced plasma drug concentration → diminished effect) of a drug–drug interaction. Although multiple sources describing specific drug–drug interactions exist (e.g., primary and secondary literature, drug product labeling), the information may not be complete or updated. In examining multiple information sources pertaining to this topic, the authors found a data compilation from Indiana University (http://medicine.iupui.edu/clinpharm/ddis/) to be the most complete and clinically useful. Utilizing primary literature should be assessed when information is not available in online sources.

Drug interactions may also occur at a pharmaceutical level as a result of a physicochemical incompatibility of two medications when combined. Such interactions generally alter the chemical structure of 1 or both constituents, thereby rendering them inactive and potentially dangerous (e.g., intravenous infusion of a crystalline precipitate or unstable suspension). For example, ceftriaxone should be avoided in infants younger than 28 days of age if they are receiving or are expected to receive intravenous calcium-containing products because of reports of neonatal deaths resulting from crystalline deposits in the lungs and kidneys. Alternatively, 2 drugs simultaneously administered perorally may form a complex that can inhibit drug absorption (e.g., coadministration of doxycycline with a food or drugs containing divalent cations).

Nonprescription preparations, herbal supplements, and certain foods also have the potential to produce interactions with drugs. These are often quite challenging for the clinician, especially for alternative therapies, in that their composition (or potency) may not be completely discernable from the product labels and because the disposition of many natural products has not been studied in either children or adults. Many patients and their parents also do not consider alternative

therapies (including nutraceuticals) to be "medicines" (and, consequently, will not disclose their use during a routine medication history) but to be safe "nutritional supplements" despite absent regulation for their testing. Consequently, a patient visit should begin with a thorough medication history that includes discussions of which nonprescription medications and herbal products are being used and their regularity of use. This allows the clinician to identify the primary ingredients contained in these products and query their potential for producing clinically significant drug–drug interactions. This can be efficiently accomplished through available web-based search engines (e.g., Natural Medicines Comprehensive Database, http://naturaldatabase.therapeuticresearch.com/home.aspx).

One of the most daunting challenges for the clinician is not to determine whether a drug–drug or drug–food interaction may be present, but if it will be of sufficient magnitude so as to be clinically significant. Extensive databases of reported and/or potential (e.g., theoretical mechanism- or metabolism-based) drug interactions exist and are widely available via the Internet (e.g., http://www.medscape.com/druginfo/druginterchecker; http://www.drugs.com/; http://www.umm.edu/adam/drug_checker.htm), some of which provide some assessment as to their potential significance. Many computer-based proprietary information systems used by hospital and community pharmacies are routinely used to screen a patient's medication profile (generally restricted to prescribed drugs) against new prescriptions to evaluate the potential for drug–drug interactions.

The provision of individualized, optimal drug therapy requires that the clinician make an assessment of potential drug–drug interactions and their significance. This requires knowledge of the interaction, the patient's condition, concomitant treatments (prescriptions, nonprescription drugs, alternative medicines), the impact of development on the dose– concentration–response relationship and a consideration of the risk-vs-benefit profile of the drug being prescribed. The clinician must be cognizant that if the clinician treats a potential drug–drug interaction as an absolute contraindication to drug use, it is possible that an alternative drug choice could produce a treatment associated with either less benefit or greater risk. Although many drugs have the potential to cause drug interactions, not all those documented may be clinically relevant for a given patient. *For patients with complex histories who require treatment with multiple medications, consultation with a clinical pharmacologist or pharmacist can help provide guidance on drug–drug interactions and their potential to impact therapy.*

Adverse Drug Reactions

Adverse drug reactions (ADRs) have been defined by the World Health Organization as "a response to a drug that is noxious and unintended, and occurs at doses normally used in man for the prophylaxis, diagnosis or therapy of disease or for the modification of physiological function." There are 2 traditional pharmacologic classifications of ADRs: type A and type B. Type A reactions are dose dependent, predictable, and account for 85-90% of all ADRs. These are often considered as "side effects" to medications. Type B reactions are not dose dependent, are unpredictable and account for approximately 10-15% of all adverse reactions. These are generally considered to represent hypersensitivity (i.e., allergic) reactions whereas some can have a nonimmune basis. Historically, such standardized definitions describing adverse events have not been routinely utilized. Furthermore, patients sometimes misinterpret some side effects as allergies (e.g., diarrhea with amoxicillin/clavulanate) and this may be perpetuated through the patient's medical record, thus potentially restricting a useful and necessary medication.

In the pediatric population, ADRs are common occurrences that produce a major burden to patients and the healthcare system. Studies concerning ADRs in pediatric patients suggest the following: (1) approximately 9% of all pediatric patients admitted to the hospital experience an ADR during their treatment; (2) the apparent incidence of ADRs in children in outpatient clinics is approximately 1.5%; (3) ADRs have been reported as being responsible for >2% of pediatric admissions to children's hospitals; and (4) approximately 40% of ADRs occurring in hospitalized children are potentially life-threatening. In considering these "statistics" it should be recognized that the true incidence of ADRs in children is not known as a consequence of generalized underreporting by healthcare providers (physicians, nurses, pharmacists), parents/caregivers, and patients (who may not recognize signs/symptoms and/or be unable to report them), and in many countries (including the United States), the lack of a standardized surveillance and real-time reporting system. As a consequence, estimation of their incidence relies upon spontaneous, volunteer reporting systems that lack uniformity and critical evaluation and do not provide both numerator and denominator data necessary to determine true incidence of a specific ADR in a specific subpopulation of patients.

Despite the limitations associated with determining the incidence of ADRs in children, it is estimated that their occurrence in patients 0-4 yr of age (3.8%) is more than double that seen at any other time throughout childhood and adolescence. The reasons for this are not currently known but may involve developmental differences in pharmacokinetics and/or pharmacodynamics (i.e., altered dose–concentration–effect relationship), age-associated differences in physiologic "systems" that modulate drug and/or metabolite-mediated cellular injury (e.g., the immune system) and/or the therapeutic use of drugs known to have a relatively high incidence of producing ADRs (e.g., delayed hypersensitivity reactions associated with β-lactam antibiotics). Also, it is important to recognize that infants can experience ADRs from drugs that are not administered to them therapeutically, but from incidental drug exposure (e.g., transplacental drug passage, breastfeeding). Examples include neonatal abstinence syndrome associated with maternal opiate use, production of a hyperserotonergic state in neonates born to mothers who received selective serotonin reuptake inhibitors during and through pregnancy, and opiate toxicity in breastfed infants whose mothers were taking codeine for pain management. In these instances, drug accumulation occurring because of reduced activity of drug-metabolizing enzymes associated with development, and, potentially, pharmacogenetically determined phenotypic changes that, in concert, can produce a level of systemic drug exposure sufficient to produce exaggerated drug response or frank toxicity.

There are also specific ADRs that occur at a much greater frequency in infants and children as compared to adults. Examples include aspirin-associated Reye syndrome, cefaclor-associated serum sickness-like reactions, lamotrigine-induced cutaneous toxicity, and in infants younger than 2 yr of age, valproic acid–induced hepatotoxicity. It is not clear whether the age predilection for these specific ADRs is associated with developmental differences in drug biotransformation related to both metabolite formation and detoxification or, alternatively, has a pharmacogenetic basis. Finally, it should be recognized that children, like adults, do experience hypersensitivity reactions to drugs. Examples include reactions to anticonvulsant drugs (e.g., phenytoin, carbamazepine, phenobarbital), sulfonamides (e.g., sulfamethoxazole, sulfasalazine), minocycline, cefaclor, and abacavir. These specific ADRs are not characteristic of type I (i.e., immediate) hypersensitivity reactions (e.g., true penicillin allergy) or anaphylactoid reactions; rather, they represent delayed hypersensitivity reactions that are classified as idiosyncratic with respect to their origin. A relatively common constellation of symptoms (fever, rash, and lymphadenopathy) suggests that abnormal activation/regulation of the immune system is a predominant component of their pathogenesis. Data from in vitro studies of sulfamethoxazole hypersensitivity also support this assertion. A requisite role for metabolic bioactivation (for anticonvulsants, sulfamethoxazole, and cefaclor) and, possibly, genetic factors, such as allelic variants in HLA-B (e.g., HLA-B*5701 and HLA-B*1502 associated with hypersensitivity reactions to abacavir and carbamazepine) appear also to be involved in their etiology.

PERSONALIZED MEDICINE

See also Chapter 59.

The general concept of personalized medicine involves the application of genomic information to predicting a disease, disease severity, and therapeutic response. This "new vision of medicine" has been described as the 3 Ps: predictive, personalized, and preventive. However, in children, ontogeny should also be considering when

discussing personalizing therapeutic treatments. Thus, the aim of pediatric personalized medicine is to uniquely combine genetic variation with developmental stage to provide a tailored approach to either drug avoidance (in the case of predicted, significant risk of an ADR) or treatment.

Chapter 61

Anesthesia, Perioperative Care, and Sedation

Randall C. Wetzel

The primary purpose of general anesthesia is to suppress the conscious perception of, and physiologic response to, noxious stimuli and to render the patient unconscious. Potent drugs are used to blunt physiologic responses to what would otherwise be life-threatening trauma (surgery). Intraoperatively, the anesthesiologist is responsible for providing analgesia as well as physiologic and metabolic stability (Table 61-1). This responsibility is facilitated by obtaining an adequate preanesthesia history (Table 61-2). Although anesthetic risk has greatly decreased, the increased risk of morbidity and mortality in the perioperative period demands the utmost vigilance. The risk is even higher in certain disease states (Table 61-3).

GENERAL ANESTHESIA

Analgesia

Providing analgesia for procedures both in and out of the operating room is a major responsibility and functions within a spectrum of care (Table 61-4). Techniques exist to provide profound pain relief during operative procedures for all patients, including the most critically ill infants. Blunting the physiologic responses to painful stimuli inhibits the stress response and its multiple deleterious physiologic and metabolic consequences. The response to painful and stressful stimuli is a potent stimulus of the **systemic inflammatory response syndrome,** which leads to increased catabolism, physiologic instability, and increased mortality (see Chapter 70). Appropriate use of medication, such as fentanyl anesthesia in neonates, reduces the incidence of postoperative bradycardia, hypotension, acidosis, interventricular hemorrhage, coagulation abnormalities, hypoglycemia, and death.

Hypnosis and Amnesia

The blunting of both consciousness **(hypnosis)** and conscious recall **(amnesia)** is a crucial feature of pediatric anesthesia care. Awareness of painful, anxiety-provoking, and stressful conditions for children is

Table 61-1	Goals of Anesthesia
Analgesia	
Amnesia and a decreased level of consciousness	
Akinesia–absence of movement in response to painful stimuli	
Physiologic support and homeostatic management throughout the perioperative process	
Vigilance	

Table 61-2 The Preanesthetic History

Child's previous anesthetic and surgical procedures:
- Review the anesthetic record for information about the mask and endotracheal tube size; the type and size of laryngoscope used; difficulties with mask ventilation or intubation; prolonged emergence (awakening) from anesthesia; postoperative vomiting, postoperative agitation and disordered postoperative behavior in the days following anesthesia/surgery. In addition, a history of hyperthermia or acidosis in the child or family member should be sought.

Perinatal problems (especially for infants):
- Need for prolonged hospitalization
- Need for supplemental oxygen or intubation and ventilation
- History of apnea and bradycardia
- History of cardiovascular compromise

Other major illnesses and hospitalizations

Family history of anesthetic complications, malignant hyperthermia, or pseudocholinesterase deficiency

Respiratory problems:
- Long-term exposure to environmental tobacco smoke
- Obstructive apnea, breathing irregularities, or cyanosis (especially in infants younger than 6 mo of age)
- History of snoring or an obstructive breathing pattern
- Recent upper respiratory tract infection
- Recurrent respiratory infections
- Previous laryngotracheitis (croup) or laryngomalacia
- Asthma or wheezing during respiratory infections
- Airway abnormalities, facial anomalies, mucopolysaccharidosis

Cardiac problems:
- Murmur or history of congenital heart disease—ask for details
- Dysrhythmia
- Exercise intolerance
- Syncope
- Cyanosis

Gastrointestinal problems:
- Reflux and vomiting
- Feeding difficulties
- Failure to thrive
- Liver disease

Exposure to exanthems or potentially infectious pathogens

Neurologic problems:
- Seizures
- Developmental delay
- Neuromuscular diseases
- Increased intracranial pressure

Hematologic problems:
- Anemia
- Bleeding diathesis
- Tumor
- Immunocompromise
- Prior blood transfusions and reactions

Renal problems:
- Renal insufficiency, oliguria, anuria
- Fluid and electrolyte abnormalities

Psychosocial considerations:
- Posttraumatic stress
- Drug abuse, use of cigarettes or alcohol
- Physical or sexual abuse
- Family dysfunction
- Previous traumatic medical or surgical experience
- Psychosis, anxiety, depression

Gynecologic considerations:
- Sexual history (sexually transmitted infections)
- Possibility of pregnancy

Current medications:
- Prior administration of corticosteroids

Allergies:
- Drugs
- Iodine
- Latex products
- Surgical tape
- Food (especially soya and egg albumin)

Dental condition (loose or cracked teeth)

When and what the child last ate (especially in emergency procedures)

Table 61-3 Specific Pediatric Diseases and Their Anesthetic Implications

DISEASE	IMPLICATIONS
RESPIRATORY SYSTEM	
Asthma	Intraoperative bronchospasm that may be severe and even fatal Preoperative control is essential Pneumothorax or atelectasis Optimal preoperative medical management is essential; preoperative steroids may be required
Difficult airway	Special equipment and personnel may be required Should be anticipated in children with dysmorphic features or acute airway obstruction, as in epiglottitis or laryngotracheobronchitis or with an airway foreign body Patients with Down syndrome may require evaluation of the atlantooccipital joint Patients with storage diseases may be at high risk
Bronchopulmonary dysplasia	Barotrauma with positive pressure ventilation Oxygen toxicity, pneumothorax a risk
Cystic fibrosis	Airway reactivity, bronchorrhea, increased intraoperative pulmonary shunt and hypoxia Risk of pneumothorax, pulmonary hemorrhage Atelectasis, risk of prolonged postoperative ventilation Patient should be assessed for cor pulmonale
Sleep apnea	Pulmonary hypertension and cor pulmonale must be excluded Careful postoperative observation for obstruction required
CARDIAC	Need for antibiotic prophylaxis for bacterial endocarditis Use of air filters; careful purging of air from the intravenous equipment Physician must understand the effects of various anesthetics on the hemodynamics of specific lesions Preload optimization and avoidance of hyperviscous states in cyanotic patients Possible need for preoperative evaluation of myocardial function and pulmonary vascular resistance Provide information about pacemaker function and ventricular device function
HEMATOLOGIC	
Sickle cell disease	Possible need for simple or exchange transfusion based on preoperative hemoglobin concentration and percentage of hemoglobin S Importance of avoiding acidosis, hypoxemia, hypothermia, dehydration, and hyperviscosity states
Oncology	Pulmonary evaluation of patients who have received bleomycin, *bis*-chloroethyl-nitrosourea, chloroethyl-cyclohexyl-nitrosourea, methotrexate, or radiation to the chest Avoidance of high oxygen concentration Cardiac evaluation of patients who have received anthracyclines; risk of severe myocardial depression with volatile agents Potential for coagulopathy
RHEUMATOLOGIC	Limited mobility of the temporomandibular joint, cervical spine, arytenoid cartilages Careful preoperative evaluation required Possible difficult airway
GASTROINTESTINAL	
Esophageal, gastric	Potential for reflux and aspiration
Liver	High overall morbidity and mortality in patients with hepatic dysfunction Altered metabolism of many anesthetic drugs Potential for coagulopathy and uncontrollable intraoperative bleeding
RENAL	Altered electrolyte and acid–base status Altered clearance of many anesthetic drugs Need for preoperative dialysis in selected cases Succinylcholine to be used with extreme caution and only when the serum potassium level has recently been shown to be normal
NEUROLOGIC	
Seizure disorder	Avoidance of anesthetics that may lower the seizure threshold Optimal control ascertained preoperatively Preoperative serum anticonvulsant measurements
Increased intracranial pressure	Avoidance of agents that increase cerebral blood flow Avoidance of hypercarbia
Neuromuscular disease	Avoidance of depolarizing relaxants; at risk for hyperkalemia Patient may be at risk for malignant hyperthermia
Developmental delay	Patient may be uncooperative during induction and emergence
Psychiatric	Monoamine oxidase inhibitor (or cocaine) may interact with meperidine, resulting in hyperthermia and seizures Selective serotonin reuptake inhibitors may induce or inhibit various hepatic enzymes that may alter anesthetic drug clearance Illicit drugs may have adverse effects on cardiorespiratory homeostasis and may potentiate the action of anesthetics
ENDOCRINE	
Diabetes	Greatest risk is unrecognized intraoperative hypoglycemia; if insulin is administered, intraoperative blood glucose level monitoring needed; glucose and insulin must be provided, with adjustment for fasting condition and surgical stress
SKIN	
Burns	Difficult airway Risk of rhabdomyolysis and hyperkalemia from succinylcholine following burns for many months Fluid shifts Bleeding Coagulopathy
IMMUNOLOGIC	Retroviral drugs may inhibit benzodiazepine clearance Immunodeficiency requires careful infection control practices Cytomegalovirus-negative blood products, irradiation, or leukofiltration may be required
METABOLIC	Careful assessment of glucose homeostasis in infants

Table 61-4 Definitions of Anesthesia Care

MONITORED ANESTHESIA CARE A specific anesthesia service in which an anesthesiologist has been requested to participate in the care of a patient undergoing a diagnostic or therapeutic procedure. Monitored anesthesia care includes all aspects of anesthesia care: a preprocedure assessment, intraprocedure care, and postprocedure anesthesia management. During monitored anesthesia care, the anesthesiologist or a member of the anesthesia care team provides a number of specific services, which may include some or all of, but are not limited to, the following: • Discussing anesthesia care with the family and child, obtaining consent, allaying anxiety and answering questions—family centered anesthesia care. • Monitoring of vital signs, maintenance of the patient's airway, and continual evaluation of vital functions. • Diagnosing and treating clinical problems that occur during the procedure. • Administering sedatives, analgesics, hypnotics, anesthetic agents, or other medications as necessary to ensure patient safety and comfort. • Providing other medical services as needed to accomplish the safe completion of the procedure. Anesthesia care often includes the administration of medications for which the loss of normal protective reflexes or loss of consciousness is likely. *Monitored anesthesia care* refers to those clinical situations in which the patient remains able to protect the airway for the majority of the procedure. If the patient is rendered unconscious and/or loses normal protective reflexes for an extended period, this is considered a general anesthetic.
LIGHT SEDATION Administration of anxiolysis and/or analgesia that obtunds consciousness but does not obtund normal protective reflexes (cough, gag, swallow, hemodynamic reflexes), or spontaneous ventilation.
DEEP SEDATION Sedation that obtunds consciousness and normal protective reflexes or possesses a significant risk of blunting normal protective reflexes (cough, gag, swallow, hemodynamic reflexes), hemodynamic and respiratory insufficiency may occur.
GENERAL ANESTHESIA Administration of hypnosis, sedation, and analgesia that results in the loss of normal protective reflexes.
REGIONAL ANESTHESIA Induction of neural blockade (either central, neuraxial, epidural, or spinal; or peripheral nerve block, e.g., digital nerve block, brachial plexus block), which provides analgesia and is associated with regional motor blockade. Consciousness is not obtunded. Special expertise is required. Frequently, in children, anxiolysis and sedation are also necessary for this technique to be successful. Regional anesthesia (e.g., caudal epidural blockade) is used to supplement general anesthesia and provide postoperative analgesia.
LOCAL ANESTHESIA Provision of analgesia by local infiltration of an appropriate anesthetic agent. Does not require the presence or involvement of an anesthesiologist, although an anesthesiologist may provide local anesthesia services.
NO ANESTHESIOLOGIST An anesthesiologist will not be involved in the care of the child in any way.

just as deleterious, physically and psychologically, as the painful procedures themselves. Management is aimed at blunting the fear and emotional response during surgery, painful procedures (bone marrow aspiration, lumbar punctures), or nonpainful but anxiety-provoking procedures (MRI, CT). Many drugs provide anxiolysis, blunting of recall, and amnesia for such events (Table 61-5). Obtundation of consciousness may accompany the provision of analgesia. Hypnotic and sedative agents can induce altered consciousness without producing any analgesia; *analgesia* and *obtunded consciousness* are not synonymous. It is also possible to provide analgesia (local, spinal, or epidural analgesia) without obtunding consciousness.

Sedation describes a medically induced state that is on a continuum between the fully alert, awake state and general anesthesia (see Table 61-4). In addition to inducing unconsciousness and amnesia, general anesthesia obtunds or ablates critical physiologic reflexes; the most important are **airway-protective reflexes:** coughing, gagging, and swallowing. Cardiorespiratory reflexes are also obtunded with general anesthesia; respiratory depression and hemodynamic compromise may occur and may be profound. As sedation deepens toward general anesthesia, loss of airway patency, loss of airway-protective reflexes, and loss of cardiovascular stability occur. *Light (minimal) sedation* is anxiolysis without loss of these reflexes or airway patency. *Deep sedation* occurs when these reflexes are obtunded or lost (see Table 61-4). **Adequate sedation in children may be accompanied by the actual or potential loss of vital reflexes**. It is mandatory that those providing sedation for a child be able to detect the transition into deep sedation and general anesthesia and be prepared to manage the child's airway and circulation, and provide CPR if required.

Akinesia (Immobility or Muscular Relaxation)

Akinesia is the absence of movement. It is necessary to ensure safe and adequate operative conditions and to provide ideal conditions for advanced and meticulous surgery. Akinesia is often produced with muscle relaxants (see Table 61-5). These agents facilitate respiratory management in the perioperative period and in critically ill patients. The absence of movement is neither the absence of pain nor the presence of amnesia. **Whenever neuromuscular blocking agents are used, analgesia and sedation must be provided.**

Physiologic Support

The need for anesthesia increases the need to monitor and support physiologic integrity and homeostasis. Sedation and anesthesia have significant and potentially life-threatening physiologic consequences (see Tables 61-4 and 61-5). Maintenance of adequate cardiorespiratory function, fluid management, electrolyte control, thermoregulation, and concern for all aspects of the child's health are critical during anesthesia.

Vigilance

Constant, critical attention by physicians who understand the demands of the surgical procedure, as well as the changes in physiologic status and their implications, is mandatory to provide safe perioperative care

Table 61-5 Selected Drugs Used in Anesthesia

DRUG	USES AND IMPLICATIONS
MUSCLE RELAXANTS	
Succinylcholine	Used to facilitate endotracheal intubation and maintain muscle relaxation in emergency situations; now virtually never given routinely A depolarizing neuromuscular blocking agent with rapid onset and offset properties Associated with the development of malignant hyperthermia in susceptible patients Degraded by plasma cholinesterase, which may be deficient in some individuals; such a deficiency may result in prolonged effect Fasciculations may be associated with immediate increases in intracranial and intraocular pressures as well as postoperative muscle pain
Vecuronium, rocuronium, mivacurium, *cis*-atracurium, all aminosteroids	Nondepolarizing neuromuscular blockers Have less-rapid onset than succinylcholine but are longer-acting Prolonged ICU use may lead to profound muscle weakness Vecuronium and rocuronium are metabolized by the liver and excreted in bile; they are the most commonly used neuromuscular blocking agents *cis*-Atracurium is metabolized by plasma cholinesterase and therefore may be of benefit in patients with hepatic or renal disease
HYPNOTICS	
Propofol	Rapidly acting hypnotic; amnestic, but not analgesic, a general anesthetic agent Like pentothal, may cause hypotension Causes respiratory depression May increase the seizure threshold Great utility in titrated doses for sedation and with local anesthetic and short-acting opioid for outpatient procedures May suppress nausea Associated with the often fatal propofol infusion syndrome when used in prolonged intravenous infusion (>24 hr) and therefore not used for ICU sedation in children
Etomidate	Cardiovascular stability on induction with no increase in intracranial pressure Inhibits corticosteroid synthesis and increases ICU mortality Associated with myoclonus, potential difficulty with assisted ventilation, and pain on injection
Ketamine	Hypnotic analgesic and amnestic Causes sialorrhea and should be coadministered with an antisialagogue, such as atropine or glycopyrrolate May be associated with laryngospasm Causes endogenous catecholamine release, tachycardia, and bronchodilation Increases intracranial and intraocular pressures Decreases the seizure threshold
SEDATIVE–ANXIOLYTICS	
Benzodiazepines	Produce sedation, anxiolysis, or hypnosis, depending on the dose May produce antegrade, but not retrograde, amnesia All agents raise the seizure threshold, are metabolized by the liver, and depress respiration, especially when administered with opioids Frequently administered as premedications Diazepam may be painful on injection and has active metabolites Midazolam can be administered by various routes and has a short half-life Lorazepam has no active metabolites Sedation effected by all benzodiazepines may be reversed by flumazenil, but respiratory depression may not be reliably reversed
Dexmedetomidine	Produces anxiolysis, sedation, sympatholysis, by α_2-receptor stimulation centrally; has mild analgesic properties Side effects include hypotension and bradycardia Commonly used for procedural and ICU sedation Continuous infusion for ICU sedation; currently limited to 24 hr
ANALGESIC–SEDATIVES	
Opioids	Gold standard for providing analgesia All cause respiratory depression Morphine and, to a lesser extent, hydromorphone may cause histamine release The synthetic opioids fentanyl, sufentanil, and short-acting alfentanil may have a greater propensity to cause chest wall rigidity when administered rapidly or in high doses and are also associated with the rapid development of tolerance; these 3 drugs have particular utility in cardiac surgery because of the hemodynamic stability associated with their use Remifentanil is an ultra–short-acting synthetic opioid that is metabolized by plasma cholinesterase; it may have particular utility when deep sedation and analgesia are required along with the ability to assess neurologic status intermittently
INHALATIONAL AGENTS	
Nitrous oxide	Causes amnesia and mild analgesia at low concentrations Danger of hypoxic mixture if the oxygen concentration is not monitored and preventive safety mechanisms are not in place
Potent vapors, sevoflurane, desflurane, isoflurane	"Complete anesthetics"—they induce a state of hypnosis, analgesia, and amnesia All are myocardial depressants, and some are vasodilators May trigger malignant hyperthermia in susceptible individuals Sevoflurane is almost universally used for inhalation induction of anesthesia in children All are bronchodilators at equipotent concentrations Isoflurane, and especially desflurane are associated with a higher incidence of laryngospasm, when used for anesthetic induction, than sevoflurane

for all children. Careful attention to a child's preoperative condition is mandatory for minimizing the risk during perioperative care (see Tables 61-3 and 61-4).

INDUCTION OF GENERAL ANESTHESIA

The goal of induction of general anesthesia is to rapidly achieve surgical anesthesia by using IV or, more commonly in children, inhalational induction agents. In children who are too young to tolerate the establishment of vascular access before the induction of anesthesia, it is routine to induce anesthesia by mask inhalation of volatile anesthetics. In the operating room, a child is often accompanied by the parents (parental presence during induction [PPI]) and placed on the operating room table. Before the induction of anesthesia, monitors are usually applied to the child. These include a pulse oximeter, electrocardiogram electrodes, and a blood pressure cuff. The child is then cautiously introduced to the face mask, which contains a high gas flow (5-7 L/min of oxygen), frequently mixed with nitrous oxide. Inhalation of nitrous oxide and oxygen for 60-90 sec induces a state of euphoria. The airway responses to inhalational anesthetics are now blunted, and sevoflurane can be introduced into the inhaled gas mixture. This leads to unconsciousness within 30-60 sec while the child continues to breathe spontaneously.

The child is now "asleep," and the parents can be asked to leave. An IV line is then started, and comprehensive intraoperative monitoring initiated. Surgical anesthesia can be maintained by spontaneous ventilation with a mask; this is safe only when the airway is secure and patent, the stomach is empty, and the child is older than 6 mo of age. Procedures longer than 1 hr are not usually performed with mask inhalational anesthesia. If these conditions are not met, if the surgeon needs to approach the airway, or if muscular paralysis is required, then the airway must be secured with endotracheal intubation. Although endotracheal intubation can be performed under deep inhalational anesthesia with respiratory depression and obtunded cough and gag reflexes, the depth of anesthesia required to ablate airway reflexes is very close to the level that induces hemodynamic instability. Therefore, muscle relaxation with IV, nondepolarizing muscle relaxants is induced to facilitate endotracheal intubation. *Succinylcholine is rarely, if ever, used*. After paralysis is induced, direct laryngoscopy and airway intubation can be performed. Correct endotracheal tube placement is confirmed by direct laryngoscopy, end-tidal CO_2 measurement, endotracheal tube fogging, and the finding of bilaterally equal breath sounds during positive-pressure ventilation. If necessary, fiberoptic airway endoscopy and chest radiograph, in addition to these measures, can be used to confirm correct endotracheal tube placement.

After endotracheal intubation, spontaneous ventilation may be permitted, if muscle relaxants are not used or have worn off; it is routine to provide controlled mechanical ventilation. When the child is completely anesthetized, positioned for surgery, and hemodynamically stable, and maintenance anesthesia is achieved, the surgery can begin.

Inhalational Anesthetics

General anesthesia may be induced and maintained by either inhalation or the IV route. The inhalational anesthetics used in children include sevoflurane, isoflurane, and desflurane. Although halothane is the prototypical pediatric inhalational anesthetic agent, it has been replaced by sevoflurane and is no longer used in the United States.

The *minimal alveolar concentration* (MAC) of an inhalational anesthetic is the alveolar concentration (expressed as percent at 1 atmosphere) that provides sufficient depth of anesthesia for surgery in 50% of patients. For potent inhalational agents, the alveolar concentration of an anesthetic reflects the arterial concentration of anesthetic in the blood perfusing the brain. Thus, the MAC is an indication of anesthetic potency and is analogous to the ED_{50} (effective dose in 50% of recipients) of a drug. MAC is age-dependent, is lower in premature infants than in full-term infants, and decreases from term through infancy to preadolescence. In adolescence, MAC again increases, falling thereafter. Inhalational anesthetic agents are poorly soluble in blood but rapidly equilibrate between alveolar gas and blood.

Respiratory Effects

The advantages of inhalational anesthesia are rapid onset, rapid offset, convenient route of delivery and excretion (respiratory), and the ability to provide profound analgesia and amnesia. Inhalational anesthetics are all airway irritants and, in low doses, can cause laryngospasm. All inhalational anesthetics depress ventilation in a dose-dependent manner. Thus, expired CO_2 and $Paco_2$ (arterial partial pressure of carbon dioxide) increase in spontaneously breathing children. In addition, anesthesia also decreases end-expiratory lung volume. Small lung volumes result in a decrease in lung compliance, increases in total pulmonary resistance, work of breathing, and intrapulmonary arteriovenous shunting, and a restrictive lung defect. Inhalational anesthetics also shift the CO_2 response curve to the right, thus decreasing, but not ablating, the increase in minute ventilation with increasing $Paco_2$.

Inhalational anesthetics, which may induce apnea and hypoxia in premature infants and newborns, are less frequently used in premature infants and children. In neonates and young infants, general anesthesia always necessitates endotracheal intubation and controlled mechanical ventilation. In older children, spontaneous breathing through a mask or a laryngeal mask airway without controlled ventilation is possible for shorter operations. The decreased end-expiratory lung volume and increased work of breathing always necessitate higher inspired oxygen tension.

Cardiovascular Effects

Cardiovascular effects of inhalational anesthesia include depressed cardiac output and peripheral vasodilation; hypotension is frequent. *This is accentuated in hypovolemic patients*. This hypotensive effect is more pronounced in neonates than in older children and adults. Inhalational anesthetics also decrease baroreceptor and heart rate responses. Inhalational anesthesia blunts the hypoxic pulmonary vasomotor response in the pulmonary circulation, an effect that may contribute to hypoxemia.

The net effect of inhalational anesthesia is decreased oxygen delivery. Perioperatively, catabolism is enhanced and oxygen demand is increased; there may be a profound imbalance between oxygen demand and oxygen delivery. Development of a metabolic acidosis intraoperatively may reflect this imbalance. Because the cardiovascular depressant effects of inhalational anesthesia are greater in premature and newborn infants, these agents are of limited use in such patients.

All inhalational anesthetic agents cause *cerebrovasodilation*. Sevoflurane is a more potent cerebrovasodilator than isoflurane. Thus, in children with elevated intracranial pressure, impaired cerebral perfusion, or head trauma, and in premature neonates at risk for intraventricular hemorrhage, inhalational anesthetics should be used with extreme caution. Although inhalational anesthetics decrease cerebral oxygen consumption, they may disproportionately decrease blood flow, thus worsening oxygen delivery.

Specific Anesthetics

Sevoflurane

Sevoflurane is the most commonly used inhalational anesthetic in children for both induction and maintenance of general anesthesia. It is not a significant airway irritant and leads to smoother induction than isoflurane. Emergence from sevoflurane anesthesia is quite rapid; there is a significant amount of **emergence delirium**, especially if pain has been inadequately controlled or induction was stormy and preoperative anxiety high. This effect can be blunted by pretreatment with midazolam and adequate use of opioids, although the latter delay recovery from anesthesia. Metabolism of sevoflurane yields free fluoride, which may cause renal damage; consequently, the FDA has restricted the use of sevoflurane to <2 MAC hr, preferably with fresh gas flow rates >2 L/min.

Isoflurane

Isoflurane maintains cardiac output and cerebral perfusion more effectively than sevoflurane. Isoflurane is pungent and a significant airway irritant, with an unacceptably high incidence of complications, such as laryngospasm during induction. Emergence from anesthesia with

isoflurane is quite smooth, but slower than for sevoflurane. Cerebral blood flow is only minimally affected, and cerebral oxygen delivery is maintained. Because isoflurane is not a suitable induction agent, induction with sevoflurane or with an intravenous agent, and maintenance with isoflurane is a common pediatric anesthesia practice.

Desflurane

A potent airway irritant, desflurane causes coughing, breath holding, and laryngospasm during induction and therefore is unsuitable for induction. It is frequently used for maintenance of anesthesia, and emergence from desflurane anesthesia is rapid.

Nitrous Oxide

Nitrous oxide is a tasteless, colorless, odorless gas with potent analgesic properties. It induces a state of euphoria (hence its nickname, "laughing gas"). The MAC of nitrous oxide is >100; consequently, it is not suitable as a sole agent to maintain anesthesia. Nevertheless, nitrous oxide has few complications and produces little or no hemodynamic or respiratory depression. Commonly, during maintenance of general anesthesia, the inhalational gas mixture is 70% nitrous oxide and 30% oxygen, with the addition of an inhalational anesthetic or potentiation of analgesia with an opioid or a hypnotic agent. The deleterious effects of nitrous oxide are increased postoperative nausea and vomiting and, with long-term use (days), bone marrow suppression. Although there is no evidence of harmful sequelae of the use of nitrous oxide for routine anesthesia, its use has decreased because of the greater incidence of nausea and vomiting associated with it. Nitrous oxide is a potent analgesic that is safely used in a mixture of 50% nitrous oxide and oxygen (Entonox) in obstetrics and in emergency departments to provide analgesia. Although this combination appears to be safe, it potentiates the respiratory depressive effects of opioids, and its use, in combination with any other sedative, hypnotic, or opioid agent, requires very close monitoring because it may produce general anesthesia.

Intravenous Anesthetic Agents

Anesthesia can be both induced and maintained with either intermittent boluses or continuous infusions of IV anesthetic agents. Intravenous anesthetics include barbiturates, opioids, benzodiazepines, and miscellaneous drugs, such as propofol and ketamine. Intravenous anesthetic agents can induce anesthesia more rapidly than inhalational anesthetics, with fewer complications. Vascular access is required, so unless IV access has already been obtained, inhalation induction is the preferred route. For children arriving in the operating room with vascular access, IV induction should be routine, because it rapidly takes the child from the awake state to the anesthetized state with less psychologic and cardiorespiratory compromise than occurs with inhalational induction. All IV agents affect cardiorespiratory function. The 1 exception to this may be ketamine, which, in lower doses, releases catecholamines, which maintain cardiac function and blood pressure.

Propofol

Propofol is the most commonly used IV induction agent in pediatric anesthesiology and has a rapid onset. In doses of 2-3 mg/kg, propofol induces both respiratory depression and hypotension. Propofol can sometimes burn and itch on injection. It is formulated in 10% soy emulsion with egg emulsifiers, so is contraindicated in patients with soy or egg allergy. After induction of anesthesia, propofol is also a useful agent for maintaining hypnosis and amnesia, and can be used as a sole anesthetic agent for nonpainful procedures, such as radiation therapy, MRI, and CT studies. Combined with opioids, it provides excellent, brief anesthesia for painful procedures, such as lumbar puncture and bone marrow aspiration. Propofol is a general anesthetic agent that obtunds airway reflexes, respiration, and hemodynamic function; it should not be considered a "sedation agent." Although hemodynamic stability, and even spontaneous respirations, can be maintained with cautious propofol sedation, its use for prolonged sedation over several hours to days in children younger than 12 yr is associated with hemodynamic collapse, bradycardia, metabolic acidosis, cardiac failure, rhabdomyolysis, hyperlipidemia, profound shock, and death (**propofol infusion syndrome**). Its use for prolonged sedation (>12 hr) in the critical care setting in children is contraindicated.

Barbiturates

The most commonly used barbiturate for IV induction is sodium thiopental, although it is now rarely used. Although loss of consciousness is rapid, barbiturates do not provide analgesia. Thiopental depresses respiration, induces apnea, and can cause hypotension in the hypovolemic patient. Induction with 3-5 mg/kg of thiopental usually produces 5-10 min of unconsciousness within seconds. After IV induction with sodium thiopental, maintenance anesthesia can be established using benzodiazepines, IV opioids, or inhalational anesthetics.

Pentobarbital is commonly used for sedation in children. It is an IV drug that induces loss of consciousness. It is also a potent respiratory depressant, particularly when used in conjunction with opioids and benzodiazepines. Pentobarbital has a very prolonged effect. It is not an analgesic agent, and painful procedures cannot be performed with pentobarbital sedation without supplemental analgesia. Pentobarbital sedation that is deep enough for anxiolysis and nonpainful procedures generally results in prolonged sleep. Its potency and long duration of action make it difficult to titrate. It is not an ideal drug for sedation for short or painful procedures.

Sodium methohexital (Brevital) is another IV induction agent. It is similar to sodium thiopental and has a similar spectrum of respiratory depression.

Etomidate

Etomidate is an imidazole derivative used for the induction of anesthesia, frequently in emergency situations. Its action is not as rapid as that of propofol. The lack of cardiovascular depression has led to the use of etomidate in patients with hemodynamic compromise, cardiac disease, and septic shock. Unfortunately, by inhibition of 11β-hydroxylase, this agent depresses synthesis of both mineralocorticoids and glucocorticoids for up to 72 hr following a single induction dose. Etomidate increases mortality when used as a sedative in ICUs (for which it is now contraindicated) and when used in patients who receive merely an induction dose. Adrenal suppression by etomidate further complicates the management of the very patients with hemodynamic compromise in whom the agent has been indicated. The decision to continue use of this agent must weigh the serious risks against the short-term benefit of hemodynamic stability during anesthesia induction and sedation.

Ketamine

Ketamine rapidly induces general anesthesia that lasts for 15-30 min when given at 1-3 mg/kg IV. It has few side effects and can maintain adequate blood pressure and cardiac output. Ketamine is also effective when given intramuscularly, subcutaneously, nasally, or orally; the dose must be increased for these alternative routes. Ketamine dissociates the connections between the cortex and limbic system *(dissociative anesthesia)* by its inhibition of *N*-methyl-D-aspartate receptors, producing a unique anesthetic state. Ketamine is not only a hypnotic agent, providing obtundation and loss of consciousness, but also an analgesic agent, and can act as a sole IV agent to provide general anesthesia. With low doses of this agent, airway reflexes and spontaneous ventilation may be maintained; at higher doses, loss of airway reflexes, apnea, and respiratory depression occur. It is unwise to rely on ketamine to prevent aspiration of gastric contents during deep sedation. Intravenous ketamine is a useful general anesthetic agent for short procedures.

Ketamine produces disturbing postanesthetic dreams and hallucinations. These can occur at the time of emergence from anesthesia and for several weeks. In adults, the incidence of this effect is 30-50%; in prepubertal children, it may be 5-10%. Premedication with a benzodiazepine, such as midazolam, greatly reduces these sequelae; a benzodiazepine is routinely given to children receiving ketamine anesthesia. The other side effect of ketamine is that it is a potent secretagogue, enhancing oral and bronchial secretions. A drying agent, such as atropine or glycopyrrolate, is administered before the administration of ketamine.

A bronchial smooth muscle relaxant (bronchodilator), ketamine is a useful agent for sedating asthmatic patients and others in the ICU. Ketamine has been reported to increase intracranial pressure and therefore is not indicated in patients at risk for elevated intracranial pressure. Ketamine can increase myocardial oxygen demand and should be used cautiously in patients with impaired myocardial oxygen delivery or cardiac outflow tract obstruction.

Opioids

Opioids are superb analgesic agents, providing analgesia for painful procedures and postprocedural pain (see Chapter 62). Large doses of morphine (0.5-2 mg/kg), combined with nitrous oxide, provide adequate analgesia for painful procedures and surgery. Opioids suppress the CO_2 response, can induce apnea, and are respiratory depressants. Morphine is often associated with hypotension and bronchospasm from histamine release; it is used with caution in children with asthma. Morphine is a long-acting agent, and an equivalent dose per kilogram gives much higher blood levels in neonates than in older children, with plasma concentrations approximating 3 times those in adults. This reason for this difference is the longer elimination half-life (14 hr) in children than in adults (2 hr). Because of the prolonged activity and hemodynamic instability induced by morphine, the fentanyl class of synthetic opioids has replaced it.

Fentanyl is an effective agent to provide pain relief, analgesia, and sedation for painful procedures, with a shorter duration of action and a more stable hemodynamic profile than morphine. In equal analgesic doses, all opioids are equally potent respiratory depressants. Other anesthetic agents potentiate this respiratory depression, whether they are inhalational anesthetics or IV barbiturates or benzodiazepines.

Fentanyl use at 30-50 μg/kg obtunds the hemodynamic response to surgery and provides stable operating conditions. Effective analgesia and anesthesia can be provided with IV fentanyl in a 2-3 μg/kg bolus followed by a 1-3 μg/kg/hr continuous infusion. Hemodynamic effects can be blunted and recall totally obtunded with use of a nitrous-narcotic anesthetic technique, although muscle tone may remain high and spontaneous movements can occur. Nitrous-narcotic anesthetics usually are supplemented with a nondepolarizing muscle relaxant during maintenance anesthesia. If the patient will be extubated and resume spontaneous ventilation, reversal of the muscle relaxant is necessary.

Other synthetic opioids (sufentanil, alfentanil, remifentanil) are available, but fentanyl is the most commonly used opioid. Both sufentanil and alfentanil have been used for cardiac anesthesia; their potency is different from that of fentanyl. Alfentanil appears to cause an increased incidence of muscle rigidity, convulsions, and prolonged respiratory depression compared with fentanyl, and is not used in children.

Remifentanil has very rapid onset and offset of action. In doses of 0.25 μg/kg/min, surgical anesthesia can be maintained with this agent. Its short half-life and rapid offset are advantageous for rapid emergence from anesthesia. Unfortunately, its rapid offset of action also leads to postprocedural and postoperative pain and requires analgesic supplementation, frequently with an opioid, which removes the advantage of anesthesia with a short-acting opioid. Remifentanil may have a role in providing rapidly deepening anesthesia for particularly painful events or rapidly inducing analgesia. It is also used intraoperatively by continuous infusion to maintain anesthesia. It is a potent respiratory depressant and provides no postprocedural analgesia, features that limit its use.

Benzodiazepines

Benzodiazepines induce hypnosis, anxiolysis, sedation, and amnesia, and have anticonvulsant activity. In larger doses, they cause respiratory depression and apnea; they are synergistic with opioids and barbiturates in their respiratory depressant effects. Benzodiazepines are γ-aminobutyric acid agonists.

The most commonly used benzodiazepine in pediatric anesthesia is midazolam. Short acting and water soluble, it can be injected intravenously without pain. It is a potent hypnotic–anxiolytic–anticonvulsant and is approximately 4 times more potent than diazepam. In anxiolytic doses, midazolam (0.15 mg/kg) has no effect on respiratory rate, heart rate, or blood pressure, and provides excellent preoperative sedation that is frequently accompanied by amnesia. It can be administered orally, nasally, rectally, intravenously, or intramuscularly. Use of oral midazolam at a dose of 0.5-1.0 mg/kg, mixed in sweet, flavored syrup, induces anxiolysis in approximately 90% of children. This agent has no hemodynamic, oxygenation, or respiratory depressant effects at this dose level, but when midazolam is used as a sole agent, children may frequently lose their balance and head control, may have blurred vision, and, rarely, may become dysphoric. A child sedated with midazolam should not be left unattended and is not safe walking. Most children rapidly accept an inhalational anesthetic mask after oral midazolam premedication. The widespread use of preoperative oral midazolam has decreased the practice of PPI to calm younger children.

Dexmedetomidine

Dexmedetomidine is an IV agent that obtunds consciousness through central α_2-receptor stimulation, much like clonidine. It appears to cause no respiratory depression and produces anxiolysis, sedation, and mild analgesia. It is a sympatholytic, and its side effects include hypotension and bradycardia. Dexmedetomidine is commonly used for sedation in ICU patients as well as for procedures; it is being explored as an adjuvant for general anesthesia, especially in cardiac patients.

Complications During Induction of Anesthesia

The period between full wakefulness, with the child in control of airway reflexes, and general anesthesia, with total loss of control, is fraught with difficulty. During induction, laryngospasm, bronchospasm, vomiting, pulmonary aspiration of gastric contents, and subsequent aspiration pneumonitis pose a constant threat although they rarely occur. Concern about vomiting and aspiration dictates the use of preanesthetic fasting (NPO [nothing by mouth]) guidelines and indicates rapid sequence anesthetic induction.

Laryngospasm is the most common complication. During induction of anesthesia, especially with inhalational anesthetics, a period of excitement may occur. This period is associated with heightened airway reflexes, which can lead to coughing, gagging, laryngospasm, and bronchospasm. Laryngospasm is reflex closure of the larynx, which makes it impossible for the child to breathe or for assisted ventilation to be used. The child may make violent inspiratory efforts against a closed glottis, generating significantly negative intrathoracic pressure. This may affect cardiovascular function and cause postobstructive pulmonary edema. Laryngospasm can be prolonged, and hypoxia may ensue. Laryngospasm occurs in up to 2% of all anesthetic inductions in children younger than 9 yr and is half as common in older patients. Laryngospasm occurs twice as frequently in children with active or recent upper respiratory tract infection (URI). A history of passive smoking from environmental (parental) tobacco smoke increases the likelihood of laryngospasm 10-fold, and even more if the smoker is the child's mother.

Laryngospasm can be relieved during induction of anesthesia by increasing the anesthetic dosage, either intravenously or through inhalation (although with the glottis closed, further administration of inhalational anesthesia is not possible). Muscle relaxation relieves laryngospasm, and in an acute situation, this situation may be an indication for succinylcholine. Constant positive airway pressure administered by someone skilled in airway management to ensure patency of the soft tissues of the oropharynx may be beneficial in alleviating laryngospasm. Laryngospasm may also occur during emergence from anesthesia, because a state of excitement is again traversed between deep anesthesia and wakefulness.

Bronchospasm can occur during induction, either in response to histamine release as a result of many of the anesthetic agents or as part of a hyperexcitable stage. Endotracheal intubation may also induce bronchospasm during induction. Bronchospasm during induction is particularly common in children with asthma. Bronchospasm secondary to intubation in a patient with reactive airway disease can be severe, may be associated with life-threatening hypoxemia, and may make it

impossible to ventilate the child. The use of histamine-releasing anesthetic agents has been associated with total airway obstruction, respiratory failure, and cardiac arrest. Environmental tobacco smoke is a risk factor.

Other pulmonary problems with induction of anesthesia include massive atelectasis with hypoxemia, impaired ventilation and perfusion, blunted hypoxic pulmonary vasoconstriction, and increased airway secretions with decreased bronchociliary function. **Hypersecretion** is prevented by the routine use of antisialagogues, such as atropine. The newer inhalation agents are less-potent secretagogues, and the use of atropine premedication is much less common, but is probably indicated if ketamine is used.

Hemodynamic complications upon anesthesia induction include **hypotension,** which can be profound in hypovolemic patients; decreased myocardial function, which can be severe in patients with compromised cardiac function; and tachycardia and cardiac dysrhythmias. Inhalational anesthetics sensitize the myocardium to circulating catecholamines, and induction and excitement are associated with a hypercatecholaminergic state.

Parental Presence During Induction of Anesthesia

Parents may expect to be with their child during the induction of anesthesia. Removing a terrified child from the comforting arms of a parent is stressful for the child, the parent, and the caregivers. If this parental separation cannot be achieved comfortably with preoperative psychoprophylaxis and behavioral modification, including education and desensitization to the operative environment, or with pharmacologic aids, such as preoperative medications including benzodiazepine and barbiturates, then there may be a need to defer parent–child separation until general anesthesia is induced. Preoperative medication with oral benzodiazepine more frequently provides calm, smooth induction conditions than PPI without pharmacologic preparation. Although the use of PPI in the hands of a confident, competent anesthesia practitioner can replace the need for preoperative medication, it does not reliably predict smooth induction. PPI appears to decrease neither emergence phenomena nor the incidence of postoperative behavioral changes, and it does not appear to add an advantage for the child over that provided by preoperative sedative medication, such as with oral midazolam.

MAINTENANCE OF ANESTHESIA

Maintenance of anesthesia is the period between induction and emergence. The child should be asleep, unaware of pain, unresponsive with either motion or hemodynamic responses to painful stimuli, and homeostatically supported. The child is comatose, without airway-protective reflexes and with suppression or absence of respiration, and has received drugs that suppress hemodynamic adaptive responses. The child is also exposed to surgical trauma, and there may be blood loss and significant fluid shifts (third spacing), decreased intravascular volume, and hypothermia.

Anesthesia is usually maintained with or without nitrous oxide, an inhalational anesthetic such as isoflurane or sevoflurane, and an opioid for intraoperative analgesia, potentiation and deepening of anesthesia, and postoperative analgesia. A benzodiazepine is added either during premedication or intraoperatively to supplement hypnosis and amnesia. A nondepolarizing muscle relaxant (vecuronium or rocuronium) completes the pharmacologic maintenance of anesthesia. Agents can be given by continuous inhalational anesthesia or by continuous or bolus IV infusion.

During maintenance, the child may breathe spontaneously through an anesthetic mask or endotracheal tube or may be mechanically ventilated. All general anesthetic agents decrease end-expiratory lung volume, which is generally lower than functional residual capacity, with increases in pulmonary closing capacity and intrapulmonary shunt. Hypoxia would occur without supplemental oxygenation. These effects are compounded by respiratory depressant effects and the depressed CO_2 response curve. Therefore, it is generally considered that use of anesthetics for longer than 1 hr requires endotracheal intubation and positive-pressure ventilation. For long procedures, spontaneous breathing through a mask is possible; in smaller children, in whom the surgical field and the airway may be close together, the need to maintain a patent airway necessitates endotracheal intubation.

Muscle relaxation to facilitate endotracheal intubation was once accomplished with succinylcholine. This agent has a high-risk profile, however, and is associated with postoperative pain (muscle spasms); hyperkalemia; elevated intracranial, intraocular, and intragastric pressures; malignant hyperthermia; and myoglobinuria and renal damage. Succinylcholine is now rarely used, except to provide rapid relief of laryngospasm. Intubation of the airway is facilitated with a nondepolarizing, short-acting muscle relaxant. Rocuronium is the drug most commonly used for intubation. For procedures that last longer than 40 min, vecuronium and alcuronium are suitable to induce muscle relaxation for intubation. After intubation of the airway, the decision must be made whether to maintain muscle relaxation to facilitate surgery or to allow the child to resume spontaneous respiration. Prolonged use of a nondepolarizing muscle relaxant is common practice but may contribute to postoperative respiratory compromise if it is not fully reversed with appropriate agents.

Reversal of neuromuscular blockade is standard anesthetic practice. Effects of nondepolarizing muscle relaxants are reversed by increasing the concentration of acetylcholine with neostigmine (acetylcholine esterase inhibitor) and either atropine or glycopyrrolate to prevent the vagal effects. With the virtual abandonment of succinylcholine, only nondepolarizing muscle relaxants are routinely used for intubation. The termination of their action depends on metabolism and elution away from the neuromuscular junction. This process, even for the shortest-acting muscle relaxants (rocuronium), can take several minutes. An intubating dose of rocuronium to rapidly induce paralysis in emergency situations may not spontaneously reverse for 20 min or longer (compared with ≈3 min for succinylcholine). If the airway cannot be secured, disaster may follow in the child who is unable to breathe spontaneously and in whom blockade cannot be reversed.

Thermoregulation is critical during anesthesia. The absence of movement and the inhibition of shivering lead to difficulty in thermogenesis. All the contributors to heat loss—convection, radiation, evaporation, and conduction—occur during anesthesia. Humidification and warming of inspired air are required. Additional warming devices are commonly used, such as rewarming blankets. General anesthetic agents increase the interthreshold range (the minimal temperature change that will lead to sympathetic response, generally 0.3°C [0.5°F]). Although temperature sensing may remain normal, an autonomic response to hypothermia is not triggered. Anesthetic agents cause vasoparesis, which further impairs thermoregulation and increases heat loss. In newborns, inhalational anesthetics inhibit nonshivering thermogenesis from brown fat, putting them at higher risk for hypothermia.

Fluid Maintenance During Surgery and Anesthesia

Patients who are unconscious and immobile have lost venous pump mechanisms and have peripheral venous pooling. Anesthetic agents cause vasodilation, and anesthetized patients have relative hypovolemia. Intravascular volume expansion is frequently required after the induction of anesthesia to maintain adequate perfusion, tissue oxygenation, urine output, and blood pressure. Volume expansion is most commonly provided by isotonic salt-containing solutions (normal saline, lactated Ringer solution). Autonomic responses may be increased as part of the surgical stress response, with vasoconstriction and intravascular volume contraction caused by diuresis, intravascular volume loss from hemorrhage, evaporation (insensible loss, increased during surgery), and third space (interstitial space) fluid losses resulting from the inflammatory response. Abnormalities in the distribution of renal blood flow and secretion of antidiuretic hormone further complicate the regulation of intravascular volume.

The concern about **hypoglycemia** as a result of preoperative fasting led to the recommendation that infants and small children receive

Table 61-6	Intraoperative Pediatric Fluid Replacement
4 mL/kg/hr	1-10 kg
2 mL/kg/hr	10-20 kg
1 mL/kg/hr	per kg >20 kg
Example: a 22-kg child requires: (4 × 10) + (2 × 10) + (1 × 2) = 62 mL/hr	

isotonic solutions with 5% glucose. The occurrence of hyperglycemia and potential neurologic injury during cardiopulmonary bypass, or during neurosurgery and other situations in which central nervous system injury can occur, however, along with the recognition that hypoglycemia is rare in nonneonates, has called into question the routine use of glucose-containing solutions. In neonates, glucose monitoring during and after anesthesia is indicated. In older children with normal nutritional status, isotonic salt solutions without additional glucose are adequate. In children who are receiving parenteral alimentation with a solution containing a high glucose concentration (>10%), continuation of the glucose concentration should be ensured to avoid rebound hypoglycemia, which would occur if the high-glucose solution was stopped.

Intraoperative fluid maintenance includes (1) current maintenance fluids and replacement of usual deficits during the NPO period; (2) replacement of third space losses; and (3) replacement of extraordinary losses (hemorrhage). Infants should receive glucose-containing isotonic fluids, such as 5% dextrose in water with either 0.25 normal saline or isotonic crystalloid solutions. Table 61-6 is a guideline for determining fluid deficits and maintenance requirements in the operating room. Fluid deficits should be replaced over the 1st 2 or 3 hr of intraoperative management. Deficits are generally calculated as the number of hours of NPO status multiplied by the hourly maintenance rate for the child. Half of this deficit is replaced during the 1st hr and half during each of the subsequent 2 hr. If hypotension or tachycardia occurs or persists in the early stages of anesthesia, more rapid replacement of the fluid deficit is indicated. The deficit is replaced with isotonic crystalloid solutions.

Third space losses are replaced with isotonic salt solutions. For large operations, such as abdominal or thoracic procedures, during which there may be a large amount of evaporative loss as well as a significant amount of third space loss, 8-10 mL/kg per hr of surgery is generally given as IV fluid replacement. For smaller operations, such as herniorrhaphy, pyloromyotomy, and minor procedures, fluid replacement at 3-5 mL/kg/hr is indicated for third space losses. Even when surgery involves the extremities and third space losses are minor, it is wise to give an additional 1-2 mL/kg/hr to replace them.

A crystalloid solution is indicated for blood loss, at 3 mL per mL of blood lost. This formula could be reduced somewhat if blood is replaced on an mL-per-mL basis with packed red blood cells or whole blood equivalent. The use of albumin or other suitable colloid, such as fresh-frozen plasma in neonatal surgery, also decreases the amount of crystalloid replacement needed for blood loss. During maintenance anesthesia, if large-volume transfusions are required, warming the blood and crystalloid solutions avoids hypothermia. With major surgery and the resultant systemic inflammatory response syndrome, capillary integrity is lost and third space losses are common. Failure to replace this third space loss and restore intravascular volume leads to hypotension, shock, acidemia, and renal failure, and further stimulates the systemic inflammatory response syndrome.

RECOVERY FROM ANESTHESIA

Recovery from anesthesia includes emergence and postoperative recovery from surgery and anesthetics. **Emergence** describes the time and the physiologic response to decreasing depth of anesthesia during return to consciousness. During emergence, patients experience decreased anesthetic effect, increased stress responses, physiologic and psychologic responses to painful stimuli, excitement, and anxiety. Conscious realization of pain may lead to physiologic responses during emergence. Normal physiologic functions, such as spontaneous ventilation, resume and hemodynamic function improves. After routine elective procedures, the child should be fully conscious before leaving the operating room, with intact airway reflexes, the ability to follow simple commands, the effects of muscle relaxants reversed, and airway patency maintained. If the child is going to the ICU, or if for surgical reasons the decision is made to leave the child intubated, analgesia and sedation should be maintained, along with mechanical ventilation, in the postoperative period. Ideally, emergence should be as brief as possible, with maintenance of analgesia and anxiolysis and restoration of cardiorespiratory function. Inhalational anesthetic agents leave the system rapidly during ventilation, and muscle relaxants can be reversed; however, the effects of opioids, benzodiazepines, and IV hypnotic agents may be prolonged.

During emergence, the decision must be made whether to reverse the effects of muscle relaxants. The effects of long-acting, nondepolarizing muscle relaxants (vecuronium and pancuronium) are invariably reversed. If the child appears to be weak or to have respiratory depression in the postoperative phase, prolonged neuromuscular blockade should be considered.

POSTANESTHESIA CARE UNIT

In the postanesthesia care unit (PACU), the child is observed until there is adequate recovery from anesthesia and sedation. Parents should be permitted to comfort their children in the PACU. Achievement of spontaneous breathing, adequate arterial saturation (>95%), and hemodynamic stability are key recovery end points. The child should be arousable, responsive, and oriented before discharge from the PACU. The amount of time spent in the PACU depends on whether the child is being discharged to an inpatient nursing unit, to an ICU, to a postrecovery area, or directly home. Discharge from the PACU depends on the child's overall functional status—not merely the physiologic end points, but also the behavioral end points as well as the adequate provision of analgesia and control of postoperative nausea and vomiting. There are several scoring systems (Table 61-7) for determining whether a child is ready to be discharged from the PACU.

Complications in the Postanesthesia Care Unit

Respiratory Depression

Prolonged emergence from anesthesia and respiratory depression can be caused by opioids or inadequate antagonism of neuromuscular blocking agents. Pain can cause significant hypoventilation, especially after thoracic or abdominal surgery. Delayed emergence from anesthesia can occur as a result of retention of inhaled anesthetic agents worsened by hypoventilation. Hypothermia, especially in neonates, delays metabolism and excretion of anesthetics and also aggravates neuromuscular blockade. If respiratory depression is profound, then maintenance of the airway may require an oral airway. If the depression is severe, endotracheal intubation and mechanical ventilation are indicated.

Only in rare cases, in which **opioid suppression** is suspected, is reversal of the effects of opioid with naloxone indicated. Opioid reversal with naloxone reverses not only the respiratory depression but also the analgesia. A somnolent child with respiratory depression may become excited, agitated in severe pain, uncontrollable, and/or hypertensive after naloxone. Opioid reversal necessitates bedside attention by the physician to monitor the child's behavioral, hemodynamic, and respiratory status. *Naloxone is shorter-acting than most opioid analgesics.*

Atelectasis is another respiratory complication occurring in the 1st 48 hr after anesthesia. Although atelectasis suggests an inhaled foreign body, it is most likely caused by secretions and decreased respiratory effort secondary to pain. Microatelectasis may lead to postoperative infections. Aspiration pneumonia is another postoperative complication.

Postoperative stridor occurs in up to 2% of all pediatric patients. The use of uncuffed, atraumatic, nonirritant endotracheal tubes has decreased the incidence of airway trauma. The use of appropriately sized endotracheal tubes and assurance of an air leak <30 cm H_2O

pressure further decreases the risk of airway trauma. A history of stridor increases the likelihood of postoperative complications. Stridor may be severe enough after extubation to require reintubation. Retractions and respiratory distress in the postoperative period should suggest this complication, and stridor or wheezing should confirm the diagnosis. Racemic epinephrine aerosols are effective therapy; their use requires prolonged observation because of the potential for recurrence of the airway obstruction. Stridor in infants suggests the need for overnight observation.

Hemodynamic instability is much less common in the PACU. Volume expansion may be required to maintain adequate blood pressure, peripheral perfusion, and urine output. Requirement for excessive volume replacement (>30 mL/kg) to maintain blood pressure, perfusion, and urine output in the postoperative period is an indication of shock and occult bleeding, and it necessitates surgical consultation.

Emergence delirium is noted in <3% of children and is more common in those 3-9 yr old. In the immediate hour after surgery, children may become extremely restless, combative, and disoriented, and may be screaming, inconsolably crying, or poorly communicative. These children pose a danger to themselves. This phenomenon is more common when barbiturates are used as part of premedication or induction and inhalational anesthetics or ketamine forms part of the maintenance anesthetic. Although disorientation is common in the postanesthetic stage, erratic, delirious behavior requires attention, with gentle restraint, a quiet environment, and comforting. Potential postoperative complications, such as hypoglycemia and hypoxemia, should be ruled out. Occasionally, it is necessary to sedate the child with benzodiazepines, although these agents prolong postanesthesia recovery time and when they wear off, emergence delirium may recur.

Awareness During Anesthesia

A primary goal of anesthesiology is obtunding consciousness to ablate awareness during procedures and recall afterward. In adults, certain anesthetic techniques are associated with an unacceptably high incidence of recall during anesthesia. Awareness and recall of events during a surgical procedure can be unpleasant and terrifying; the long-term sequelae of such recall in children are unknown. Continuous monitoring of cerebral electroencephalographic function by monitoring of the bispectral index has been recommended. Unfortunately, data in children do not confirm the efficacy of bispectral index monitoring as a means of determining anesthetic depth, and this fact, combined with the absence of meaningful data on intraoperative awareness and recall in infants and children, does not currently support the routine use of bispectral index monitoring.

Postoperative Nausea and Vomiting

After general anesthesia, 40-50% of children may experience nausea and vomiting. More than 80% of all high-risk children receiving inhalational anesthesia experience postoperative nausea and vomiting (PONV). It may occur in the immediate postoperative period, within the 1st 1-2 hr, or several hours after surgery and anesthesia. The etiology may be related to the stress and trauma of surgery combined with the emetic effects of anesthetic agents. Pain is an important cause of nausea and vomiting. Opioid analgesics also induce nausea and vomiting. Preoperative fasting does not decrease the incidence of nausea and vomiting. Indeed, hydration and glucose supplementation appear to be important factors in decreasing PONV. The use of analgesic agents other than opioids (acetaminophen, ketorolac) and regional or local anesthesia is associated with decreased PONV.

This complication prolongs recovery room times, requires significant nursing attention, and increases the use of potent antiemetic agents (ondansetron, other serotonin antagonists). Ondansetron is very efficacious as a prophylactic and in the treatment of PONV. Ondansetron and other serotonin antagonists are recommended for high-risk patients (strabismus surgery) or for actual treatment of PONV. They are contraindicated in children taking serotonin reuptake inhibitors for migraine headaches. Metoclopramide is useful prophylactically. Droperidol (which has an FDA-required black box label warning) must be used with caution because of the rare occurrence of prolonged QT interval and ventricular arrhythmias associated with its use.

Thermoregulation and Malignant Hyperthermia

For patients in the PACU, thermoregulation remains abnormal for several hours. Shivering is common in the postoperative state, and a feeling of extreme cold is common. Warm blankets are very comforting and seem to decrease shivering. **Hypothermia,** especially in neonates, leads to hypotension, bradycardia, acidosis, apnea, and prolongation of the effect of opioids and neuromuscular blocking agents. Although hypothermia has deleterious effects, rewarming must be done cautiously to avoid burning and cutaneous hyperthermia. **Hyperthermia,** with temperatures in excess of 39°C (102.2°F), is of concern in the postoperative period. If it occurs within hours of the use of an inhalational anesthetic, especially if succinylcholine was used, malignant hyperthermia must be suspected.

Malignant hyperthermia is an acute hypermetabolic syndrome that is triggered by inhalational anesthetic agents and succinylcholine. It resembles neuroleptic malignant syndrome. The onset of malignant hyperthermia may be acute, and its course may be fulminant and rapidly fatal. This condition, albeit rare (approximately 1 in 60,000 pediatric patients given anesthesia) is a constant concern. The disease is familial, and a family history of death or a febrile reaction during anesthesia should alert the anesthesiologist to its potential. Its clinical course is characterized by rapid onset of fever, acidosis, hypercarbia, and increased expired CO_2. High fever (38.5-46.0°C [101.3-114.8°F],

rising 1°C [1.8°F] every 5 min), muscle rigidity, metabolic acidosis, and hemodynamic collapse can occur. Death ensues from shock and cardiac dysrhythmias with ventricular fibrillation that is unresponsive to treatment. The mortality rate for malignant hyperthermia was once >70%. Aggressive therapy, including discontinuation of all inhalational anesthetic administration, correction of the metabolic acidosis, and treatment with the muscle relaxant sodium dantrolene, has reduced the mortality rate to <5%. Dantrolene and a kit containing supplies necessary to treat malignant hyperthermia should be present at every site where pediatric anesthesia is provided.

Malignant hyperthermia is probably genetically heterogeneous, with more than 10 genes contributing to susceptibility. Genetic mutations in the ryanodine receptor (the calcium channel of the sarcoplasmic reticulum) have been reported in 20-40% of humans with malignant hyperthermia. **Certain myopathies** are associated with the risk of malignant hyperthermia; these include Duchenne muscular dystrophy, Noonan phenotype, and, in children with a history of ptosis, squint, scoliosis, and muscle cramping. It is wise to avoid the use of succinylcholine in children with myopathies.

Malignant hyperthermia appears to occur from a massive triggering of excitation contraction coupling, sarcolemmal calcium release, and propagation of contraction by a complex biochemical process. The prolonged ischemic contraction leads to myolysis, with release of myoglobin, very high serum creatine phosphokinase levels, and renal failure secondary to myoglobinuria. Malignant hyperthermia generally occurs within the 1st 2 hr of anesthesia, but (rarely) can occur up to 24 hr later.

Certain phenomena are clues to the risk of malignant hyperthermia. The occurrence of masseter spasm during induction, with rigid clenching of the masseter muscles and an inability to open the mouth, may presage full-blown disease. Acute myoglobinuria associated with a malignant hyperthermia triggering agent is another clue. The child may not be hypermetabolic or febrile, but may have dark urine and high serum creatine phosphokinase levels, with the risk of myoglobin-induced renal tubular damage. The finding of dark urine after administration of an anesthetic requires investigation for malignant hyperthermia. An elevated creatine phosphokinase value and heme-positive urine in the absence of red blood cells in the urine indicate a need for renal protection with mannitol and alkaline diuresis.

Rapid therapy is essential. All known triggering agents must be stopped. Intravenous administration of dantrolene sodium (2.5 mg/kg IV as an initial dose) is begun as soon as possible. The need for repeated doses is indicated by the persistence of muscle rigidity, acidosis, and tachycardia, up to a maximum dose of 10 mg/kg. Once the symptoms are controlled, the patient should be observed for at least 24 hr after the laboratory values have returned to normal, because relapse can occur.

Prevention of malignant hyperthermia in susceptible patients requires the avoidance of triggering agents, which include inhalational anesthetics. Most anesthesiology departments are capable of delivering general anesthetics using anesthesia machines from which all traces of anesthetic vapors have been removed. Intravenous anesthesia and a nitrous-opioid technique are safe. Dantrolene prophylaxis is not recommended because the disease is rapidly treatable and because the drug causes respiratory depression and muscle weakness. For a child in whom malignant hyperthermia is suspected, the malignant hyperthermia hotline, 1-800-MHHYPER (1-800-644-9737), should be used to notify the Malignant Hyperthermia Association of the United States (MHAUS). The Malignant Hyperthermia Association registers susceptible patients and provides diagnostic and therapeutic information. Preanesthesia susceptibility testing includes genetic analysis of the ryanodine receptor gene, muscle biopsies, in vitro contraction studies, and, possibly, measurement of muscle CO_2 production in response to intramuscular caffeine.

Postoperative Apnea

Apnea within the 1st 48 hr after surgery and anesthesia in premature infants is common; both central apnea and obstructive apnea (mixed apnea) may occur. The use of respiratory depressants may impair respiratory control in neonates. Apnea is also a recognized stress response in neonates, and inadequate anesthesia is associated with increased apnea and respiratory complications.

The risk of postoperative apnea in premature neonates is inversely proportional to postconceptual age at the time of surgery. This risk is minimal by the time premature infants have reached the postconceptual age of 60 wk. Apnea is most common within the 1st 12 hr after surgery; postanesthetic apnea has been reported in premature infants up to 48 hr later. The incidence of apnea in full-term infants is debatable and has not been clearly demonstrated. It is generally agreed that general anesthesia should be avoided, except for emergency surgery, in full-term children younger than 44 wk postconceptual age. If surgery is required within the 1st mo of life, overnight observation and monitoring are indicated. Theophyllines decrease the incidence of postoperative apnea; they do not ablate it and therefore are not routinely used. The safest course is to monitor premature infants younger than 60 wk postconceptual age and full-term infants younger than 1 mo for at least 24 hr after anesthesia.

PREANESTHETIC EVALUATION

Most previously healthy children require minimal preoperative assessment. The American Society of Anesthesiologists (ASA) classification system for anesthetic care is the American Society of Anesthesiologists Physical Status classification (Table 61-8).

For American Society of Anesthesiologists Physical Status 1 patients, a brief history, notation of medical allergies, and a physical examination focusing on the airway, lungs, and cardiac function are sufficient. For all children who are being assessed for anesthesia risk, a family history should be obtained, for reactions to anesthetics, for drug allergies, and for sudden intraoperative death or hyperthermia after surgery, which may indicate a risk of malignant hyperthermia. In previously anesthetized children, questions should be asked regarding intraoperative anesthetic complications. The history should focus on determining whether the child is at risk for anesthetic or surgical stress as well as cardiorespiratory disease and airway compromise.

Recent URIs should be noted. A URI is an upper respiratory illness associated with fever, mucopurulent green or yellow nasal discharge, productive cough, injected sclerae, and increased mucous secretions. Clear rhinorrhea is generally not a concern. URIs can increase airway reactivity for up to 6 wk in both normal children and children with a history of reactive airway disease. URIs can also increase the risk of laryngospasm and bronchospasm, reduce mucociliary clearance, and raise the risk of intraoperative atelectasis and hypoxemia. It is generally recommended to avoid general anesthesia for elective procedures for 4-6 wk after a URI. In patients with chronic sinusitis and nasal polyps, infection should be thoroughly treated before elective anesthesia.

Acute, fatal bronchospasm can occur during induction of anesthesia and endotracheal intubation for routine, minor surgery in children with asthma. Those children at particular risk for anesthetic complications with asthma are those who were (1) admitted to the hospital within the previous year for their asthma, (2) seen in an emergency department in the last 6 mo, (3) admitted to an ICU, or (4) treated with

Table 61-8	American Society of Anesthesiology Physical Status Classification
Class 1: Healthy patient, no systemic disease	
Class 2: Mild systemic disease with no functional limitations (mild chronic renal failure, iron deficiency anemia, mild asthma)	
Class 3: Severe systemic disease with functional limitations (hypertension, poorly controlled asthma or diabetes, congenital heart disease, cystic fibrosis)	
Class 4: Severe systemic disease that is a constant threat to life (critically and/or acutely ill patients with major systemic disease)	
Class 5: Moribund patients not expected to survive 24 hr, with or without surgery	
Additional classification: "E"—emergency surgery

parenteral systemic steroids. The child should be free of wheezing for at least several days before surgery, even if this necessitates an increase in β-agonist dosage and the addition of steroids. Preoperative steroids are indicated for all children with asthma who are receiving asthma therapy or who have received such therapy within the last year. Prednisone, 1 mg/kg given 24 and 12 hr before surgery, significantly decreases airway reactivity perioperatively. Active wheezing is an indication for canceling elective surgery. If wheezing cannot be controlled on an outpatient basis with β-agonists, steroids, and other asthma therapy, then hospital admission of the child for more aggressive therapy before surgery is indicated.

Bronchopulmonary dysplasia also poses significant intraoperative risks. The same applies to cystic fibrosis and other chronic lung diseases. Every effort should be made to ensure that children with such disorders achieve the best possible respiratory status before surgery. Infections should be treated and reactive airways optimally treated without evidence of wheezing.

Airway Evaluation

Because the induction of anesthesia is associated with loss of spontaneous ventilation and airway reflexes, predicting the inability to bag-and-mask ventilate or endotracheally intubate a child before anesthesia is critical. The anesthesiologist must be told if the child has congenital anomalies that affect the airway (Table 61-9). Such anomalies include micrognathia syndromes, macroglossia syndromes, and some thoracic anomalies. Congenital anomalies associated with airway compromise should be diagnosed preoperatively. Conditions that impair mouth opening (temporomandibular joint disease) should be noted. A history of wheezing or stridor may indicate postoperative airway complications and difficult intraoperative airway management.

Mediastinal Masses

Children with anterior mediastinal masses, such as lymphomas and primary mediastinal tumors, are at serious risk for airway compromise, cardiac tamponade, and vascular obstruction. Induction of general anesthesia and even mild sedation can lead rapidly to total loss of the airway, with inability to ventilate the child and cardiovascular collapse. These patients often present in a semiemergency fashion, with the need for both a tissue diagnosis of the mass before treatment is initiated and a surgically placed central venous line.

Significant compression of vital structures can occur with seemingly mild symptoms. Tachypnea, orthopnea, wheezing, and sleep disturbances or avoidance of prone or supine positions are significant indications of serious risk. Pericardial tamponade or superior vena cava syndromes are more concerning findings. A CT scan showing >50% compression of the airway at the carina is an indication to prohibit general anesthesia and provide only mild sedation. Echocardiographic or CT evidence of pericardial tamponade, right ventricular compression, or compression of the pulmonary artery suggests severe risk.

Table 61-9 Difficult Airway Syndromes
Achondroplasia
Airway tumors, hemangiomas
Apert syndrome
Beckwith-Wiedemann syndrome
Choanal atresia
Cornelia de Lange syndrome
Cystic hygroma/teratoma
DiGeorge syndrome
Fractured mandible
Goldenhar syndrome
Juvenile rheumatoid arthritis
Mucopolysaccharidosis
Pierre Robin syndrome
Smith-Lemli-Opitz syndrome
Treacher-Collins syndrome
Trisomy 21
Turner syndrome

Biopsy with the child under local anesthesia may be indicated. If anesthesia is required, cardiopulmonary bypass should be considered, in case it becomes impossible to ventilate the child during surgery. In high-risk children, consideration should be given to initiating treatment with steroids, radiation therapy, and chemotherapy before obtaining a tissue diagnosis.

Down Syndrome

Children with Down syndrome are occasionally behaviorally difficult and are especially fearful of medical caregivers (see Chapter 81). Their cardiac anomalies, macroglossia, and upper airway obstruction can be challenging. Children with Down syndrome have atlantoaxial instability due to odontoid hypoplasia and joint laxity (see Chapter 680.3). In younger children, extension of the neck, routinely used to maintain and intubate the airway, may lead to cervical dislocation and spinal cord trauma. Some anesthesiologists recommend extension and flexion lateral neck films to detect instability before anesthesia. In children with Down syndrome, it is wise to exercise caution in stabilizing the cervical spine and also to avoid cervical flexion and extension.

Cardiovascular System

Because of the depressant effects of anesthetics and the increased metabolic demands of surgery, any compromise of myocardial function should be clearly delineated preoperatively. A preoperative electrocardiogram, an echocardiogram, and a cardiology consultation are indicated for children with a history of heart disease. An intracardiac shunt will affect oxygenation status intraoperatively. Because of the significant effect on the oxygen supply-and-demand relationship caused by general anesthesia and surgical stress, obstructive lesions, such as a valvular stenosis, must also be clearly defined. A history of cardiac dysrhythmias should be clearly understood, because inhalational anesthetics are dysrhythmogenic.

In neonates, ductus arteriosus, myocardial compromise, pulmonary edema, or congenital heart disease can significantly complicate oxygen delivery during anesthesia. Accurate diagnosis of cardiac murmurs in neonates is essential. Any preoperative cardiovascular compromise will be worsened intraoperatively and can catastrophically complicate the perioperative course.

Anemia should be diagnosed and corrected preoperatively if possible. A hematocrit value >30% is generally acceptable for routine elective anesthesia. If there are reasons to expect significant blood loss or prolonged convalescence, anemia should be corrected preoperatively. In the emergency setting, transfusion may be required. Although lower hematocrit values can be tolerated in unstressed children, the significant threat to oxygen delivery posed by anesthesia and surgery, especially if blood loss is expected, requires maintenance of an adequate hemoglobin concentration perioperatively.

Evidence of coagulopathy should be sought. Easy bruising, the use of aspirin, and familial bleeding disorders should be discussed. Intraoperative hemorrhagic bleeding can be difficult to control; massive perioperative blood transfusions have significant risk of morbidity and mortality. Preoperative correction of coagulopathic disorders is indicated. In neonates, assurance of vitamin K prophylaxis and adequate coagulation status is critical before any significant surgery. In neonates and critically ill children, adequacy of platelet count and, where indicated, coagulation factors, prothrombin time, and partial thromboplastin time should be assured.

Neurobehavioral Considerations

Seizures, significant neurologic impairment, altered level of consciousness, respiratory airway compromise secondary to neurologic disease, and neuromuscular disease should be sought and evaluated. Anticonvulsant drug metabolism is often altered perioperatively, and this change may affect anticonvulsant drug levels. Anticonvulsants may also complicate anesthetic management. Maintenance of appropriate anticonvulsant therapy postoperatively is important to avoid new seizures. Cerebrospinal fluid secretion is increased during surgery and general anesthesia. This fact is significant in patients in whom elevated intracranial pressure is suspected and in children with ventriculoperitoneal

shunts. In infants or older children with ventriculoperitoneal shunts, shunt patency and function should be assured before surgery.

Illness and the need for surgery or painful medical procedures are psychologically traumatic events for children and their families. Children are also remarkably adept at sensing stressful signals from their parents and caregivers. Many children who require anesthesia may have significant levels of fear and anxiety. Most children undergoing surgery have new-onset negative behavioral changes in the postoperative period, such as maladaptive behavioral responses that include generalized anxiety, enuresis, enhanced separation anxiety, temper tantrums, nighttime crying, and fear of strangers, doctors, and hospitals. Approximately 20% show these negative behavioral adaptations for 6 mo after surgery. Sleep quality is also altered postoperatively, resulting in further behavioral compromise.

The risk factors for postoperative behavioral changes include preoperative or induction anxiety and behaviors indicating extreme stress, as well as emergence excitation. The type of surgery may be important, with tonsillectomy and genitourinary surgery having a high incidence of postoperative behavioral changes, whereas simple procedures (tympanostomy tubes) seem to be associated with fewer changes. Another risk factor is recurrent procedures, such as anesthesia for laser surgery, strabismus surgery, or repeated eye examinations, which lead to difficult behavioral changes and have a significant effect on family dynamics.

Preoperative psychologic preparation programs decrease the incidence of postoperative behavioral changes, which last for up to 1 mo. PPI does not improve postoperative behavior. Oral midazolam (0.5 mg/kg) may decrease negative behavioral changes after surgery. Midazolam has the benefit of providing not only rapid-onset anxiolysis in 10-20 min but also very effective and rapid (10 min) amnesia.

Preoperative Preparation

The child should be in the best possible nutritional state, and nutritional supplementation, even hyperalimentation in chronically ill children, may be worthwhile.

Preoperative Fasting

Aspiration of gastric contents is a perioperative disaster and, if superimposed on lung disease, may be rapidly fatal. Aspiration may lead to laryngospasm and bronchospasm, with hypoxemia and hypoxic ischemic encephalopathy. It may also produce intraoperative atelectasis and postoperative pneumonia. It is vital to ensure that the stomach is as empty as possible before the induction of anesthesia. Acid aspiration is less likely with an empty stomach. Table 61-10 lists preoperative fasting (NPO status) guidelines.

Clear, sweet liquids (Pedialyte, 5% dextrose in water) facilitate gastric emptying, help avoid hypoglycemia, and can be given up to 2 hr before anesthesia in any child. For older infants and children, a fasting period of 4 hr for liquids provides optimal safety and minimal discomfort. Solids must be avoided for at least 8 hr before surgery. Because surgery is frequently scheduled in the morning, and for ease and clarity of understanding, the general guideline is no consumption of solids after midnight. Many conditions delay gastric emptying, and prolonged periods of fasting may be required in the presence of stress, anxiety, illness, trauma, gross obesity, or biliary atresia, or in children with delayed gastric emptying for other reasons.

Table 61-10 Guidelines for Preoperative Fasting ("2-4-6-8 Rule")*

TIME BEFORE SURGERY (hr)	ORAL INTAKE
2	Clear, sweet liquids
4	Breast milk
6	Infant formula, fruit juices, gelatin
8	Solid food

*These are general guidelines and may differ among hospitals.

The Full Stomach

Because of the serious complications of aspiration of gastric contents, it is desirable to secure the airway as rapidly as possible after obtundation in patients at risk for having a full stomach. Gastric emptying may be delayed for up to 96 hr after an acute episode of trauma or surgical illness. Under these circumstances, induction of general anesthesia and endotracheal intubation are performed in a rapid sequence (**rapid sequence induction**; see Chapter 67).

The risks of rapid sequence induction include the possibility that if the airway cannot be intubated, the child is paralyzed without a protected airway and ventilation may be hazardous or impossible. Rapid sequence induction should be performed by those who can definitely achieve endotracheal intubation quickly. It should be avoided in patients with a history of failed oral endotracheal intubation or with any of the many syndromes (micrognathia) associated with difficult intubation. Under these circumstances, bronchoscopic awake intubation may be indicated.

Before rapid sequence anesthesia induction, the child should be preoxygenated by breathing 100% oxygen for 2 min to give an extra margin of safety if intubation is difficult. The child should not receive assisted ventilation either before or after the administration of drugs because this may lead to increased gastric air and actually increase the likelihood of vomiting, regurgitation, and aspiration.

One common regimen for rapid sequence induction includes the administration of 1.5-3 mg/kg of propofol concurrently with either 0.9-1.2 mg/kg of rocuronium or 1.5 mg/kg of vecuronium. Immediately after the administration of sedation and muscle relaxants, the Sellick maneuver (cricoid pressure) should be performed by applying firm pressure in a posterior direction against the cricoid cartilage. This displaces the cricoid cartilage into the esophagus, forming an artificial sphincter to prevent reflux of the gastroesophageal contents. Cricoid pressure should be maintained until correct placement of the endotracheal tube is verified by direct visualization, fogging of the tube, and, in all circumstances, positive end-tidal CO_2.

POSTOPERATIVE PAIN MANAGEMENT

Continuation of analgesia and anxiolysis should follow surgery or painful procedures (see Chapter 62). Complete freedom from pain is not possible. Preoperative education about the surgery and a pain management plan, development of skills designed to decrease anticipatory anxiety, and active participation in treatment planning can be helpful for some children and families. Adjunctive therapy, such as virtual reality, hypnosis, pet therapy, and play therapy, also can decrease the need for potent analgesics postoperatively.

The combination of opioid and nonopioid analgesic agents and an understanding of the benefits and risks provide the foundation of pain management. A judicious combination of nonsteroidal antiinflammatory drugs, cyclooxygenase-2 inhibitors, intravenous acetaminophen, opioids, and regional analgesia has a role in postoperative pain management. Repeated evaluation is as important as the modality of pain management. Continuous and repetitive small doses of analgesia around the clock are more effective at reducing pain than occasional prn dosing intervals.

Patient-controlled analgesia (PCA), nurse-controlled analgesia, and parent-controlled analgesia are all used postoperatively (see Chapter 62). PCA provides continuous pain treatment and self-medication (vs intermittent or prn pain control) as well as control and comfort in an otherwise personally uncontrolled circumstance. PCA provides both a background low-dose infusion rate of a continuous opioid and the opportunity to supplement analgesia with bolus doses as needed. The practitioner can determine the continuous infusion rate, the bolus dose, the lockout interval, and the number of boluses per unit time that the patient may receive. PCA relies on the theory that patients cannot or will not overdose themselves because somnolence will decrease repeated self-administration. In young children, the use of the *pain button* (for pain relief) may be more difficult to ensure; children as young as 5 yr old have been able to use PCA successfully. In older children and adolescents, PCA should be a standard modality of postoperative pain management.

Regional Anesthesia

Regional anesthesia is the use of anesthetics to block the conduction of afferent neural impulses to the central nervous system. These can be local analgesic techniques, peripheral nerve blocks, nerve plexus blocks, or epidural and subarachnoid (spinal) nerve blocks. They may be administered either through a single injection (single shot) or through continuous infusion, as is common with epidural and occasionally subarachnoid blocks. They may be used for intraoperative anesthesia and postoperative analgesia, and they have the potential to decrease intraoperative analgesia and anesthetic use, as well as to provide postoperative pain management. Increased use of regional indwelling catheters to deliver continuous analgesia has shortened recovery times and hospital stays in children.

Analgesia at the site of need, without central cardiorespiratory depressant effects, can be valuable. Local anesthesia, with injection of lidocaine or bupivacaine into the affected area, can provide procedural analgesia that lasts for several hours. Infiltration of the wound site and the edges of an incision decreases postoperative pain in the initial hours after surgery. This can be performed by the surgeon at the conclusion of surgery and may supplement postoperative analgesia.

Epidural analgesia is common in pediatric practice. The epidural space lies between the dura and the pia and arachnoid membranes, an area through which all nerve roots pass. Bathing these nerve roots in local anesthetics inhibits conduction of pain impulses centrally. A single dose of epidural anesthetic may provide hours of pain relief, and a continuous infusion may provide effective pain relief for hours to days. The epidural injection of opioids can provide analgesia for 12-24 hr and is a potential supplement to postoperative analgesia.

A lumbar epidural injection is placed in the lumbar area to provide analgesia for labor and for surgery below the thorax. Caudal epidural analgesia is placed through the sacral hiatus, inferior to the distal end of the spinal cord. This is the site most commonly used for regional anesthesia and analgesia in children and is efficacious for the provision of pelvic and lower limb anesthesia as well as beneficial in orthopedic and urologic surgery. A continuous infusion of bupivacaine is the most common means of providing postoperative epidural pain relief; it may be mixed with an opioid (fentanyl or preservative-free morphine). It is also possible to provide epidural PCA with a continuous infusion pump and the ability of the patient to self-medicate with bolus prn dosing. Epidural analgesia can also provide pain relief in patients with chronic pain or pain caused by advanced malignant conditions.

The most serious complications of neuraxial anesthesia include cephalad spread of blockade with respiratory depression, paralysis of respiratory muscles, and, in extreme cases, brainstem analgesia and depression. The most common complications of neuraxial analgesia include mild discomfort; a paresthesia-like feeling of numbness and tingling; pruritus, which, if opioids are used, can be quite distressing; and occasional nausea and vomiting. Infection and epidural hematoma are extremely rare. Neuraxial opioids, especially when administered intrathecally, can cause respiratory depression; their use requires postoperative monitoring. The use of neuraxial opioids often requires treatment with antipruritic as well as antiemetic drugs.

61.1 Sedation and Procedural Pain

Randall C. Wetzel

The same drugs that induce general anesthesia are often used to provide sedation (see Table 61-5). Sedation care requires a presedation evaluation, intraprocedural monitoring, and postsedation recovery, analogous to the provision of anesthesia. Sedation is on the continuum between wakefulness and general anesthesia (see Table 61-4). The term **conscious sedation** refers to a condition in which a patient is sleepy, comfortable, and cooperative but maintains airway-protective and ventilatory reflexes. Unfortunately, for most children, this level of sedation provides little or no analgesia, and both psychologic and physiologic responses to painful stimuli persist. Sedation that is sufficient to obtund painful responses is most likely deep sedation. **Deep sedation** is a state of unarousability to voice and is accompanied by suppression of reflex responses. Management of sedated children requires vigilance and knowledge to ensure their safety and is governed by the same guidelines as anesthesia care (Table 61-11). A dose of sedative medication that causes minimal sedation in one subject may produce complete unconsciousness and apnea in another. Careful attention to guidelines for appropriate monitoring and management of sedation in children is imperative. For threatening and nonpainful procedures, anxiolysis or light sedation is frequently sufficient. For painful procedures (e.g., bone marrow aspiration, insertion of percutaneous IV catheter lines, lumbar punctures), the combination of sedation with analgesia that is required in children produces deep sedation.

Table 61-11 Systematic Approach to Sedation in Children
Thorough medical history, anticipating underlying medical problems that predispose the patient to sedation problems
Careful physical examination focused on the cardiorespiratory system and airway
Appropriate fasting
Informed consent
Pediatric drug dosing (mg/kg)
Appropriately sized equipment
A separate, dedicated observer to monitor sedated patients who may have airway compromise (induced or preexisting)
Documentation of vital signs and condition on a time-based record
Emergency backup system, "code" team, and "crash cart"
Fully equipped and staffed recovery area
Discharge criteria documenting recovery from sedation

Many specialists provide sedation and anesthesia care for children. The use of anesthetic agents is not limited to anesthesiologists, but a hospital's department of anesthesiology provides expertise in developing and managing systems of anesthesia care, including sedation. With the widespread use of the deceptively safe general anesthetic agent propofol to provide sedation, hospitals, pediatricians, and other care providers must ensure that credentialing, oversight, quality assurance, and protocols for administration of anesthetic agents provide safe care. Involvement of anesthesiologists in organizing services, training other practitioners, overseeing safety, systems, and quality, and remaining involved in the delivery of such care is sound practice. The elements of a safe system to provide procedural sedation for children are as follows:

- Defining the required knowledge set
- Defining the required skill set
- Determining the appropriate requisite training
- Ensuring adequate understanding of the drugs and their effects (desired and undesired) and interactions
- Credentialing providers
- Ensuring ongoing maintenance of skills
- Reviewing the practice
- Ensuring that the sites where anesthesia care is provided meet recognized standards
- Last but not least, overseeing a process of continuous quality improvement

Sedation with chloral hydrate (not approved by the FDA in the United States or the European Medicines Agency in the European Union), pentobarbital, or benzodiazepines is often adequate for nonpainful procedures. Nevertheless, there can be a high failure rate as well as complications by using this method, such as prolonged sedation (hours to overnight), ataxia, nausea and vomiting, desaturation, and the occasional need for rapid intervention. The temptation to add opioids and deepen sedation increases the risk of complications. The use of dexmedetomidine for procedural sedation is safe; recovery time can be prolonged, and success can be variable. The quickest way to ensure safely reversible sedation is with potent anesthetic agents.

The ultra–short-acting anesthetics (propofol, methohexital, remifentanil) provide effective procedural sedation, but their use carries a higher likelihood of inadvertent oversedation and induction of general anesthesia. These anesthetics offer efficient and rapidly reversible procedural sedation. However, their use requires the presence of an anesthesiologist and/or specially trained, experienced, and qualified physicians.

Bibliography is available at Expert Consult.

61.2 Anesthetic Neurotoxicity

Randall C. Wetzel

There is compelling experimental evidence that anesthesia-induced neurodegeneration with developmental impairment occurs in neonatal animals. Pediatric anesthesiologists have become deeply concerned by the demonstration of anesthetic-induced apoptotic neuronal cell death, central nervous system neurodegenerative changes, and their effects on the developing brain. These studies demonstrate both histopathologic changes and developmental defects from both inhalational and IV anesthetics, including isoflurane, ketamine, benzodiazepines, and propofol given to newborn animals. Combinations of drugs may cause more injury. Existing nonclinical data implicate both *N*-methyl-D-aspartate and γ-aminobutyric acid pathways in apoptosis and cell death in neonates.

The studies reporting these results were performed in animals (largely rodents), and great controversy exists concerning dose, duration of treatment, species differences, and experimental design. Although there is cause for concern and further study, alternatives to general anesthesia for many procedures in infants do not exist. Perhaps regional anesthetic techniques and narcotic-based anesthetics will be increasingly used. Interestingly, dexmedetomidine appears to block the neurotoxic effects of other anesthetics. There is insufficient current data for suggesting the safety of one anesthetic approach over another. The potential for this neurotoxicity must be balanced against the necessity of providing adequate anesthesia for neonates.

Chapter 62

Pediatric Pain Management

Lonnie K. Zeltzer, Elliot J. Krane, and Tonya M. Palermo

Pain is both a sensory and an emotional experience that, when unrecognized and undertreated, extracts a significant physiologic, biochemical, and psychologic toll. Many disease processes and most interventional procedures in pediatrics are associated with pain.

DEFINITION AND CATEGORIES OF PAIN

Pain is defined by the International Association for the Study of Pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage." The important elements of this definition to be emphasized are (1) pain encompasses both peripheral physiologic and central cognitive/emotional components and (2) pain may or may not be associated with ongoing tissue damage—pain may exist in the absence of demonstrable somatic pathology, and may rather be the acquired or genetic consequence of abnormalities of peripheral neural signaling, central modulation, or brain processing of peripheral sensations or nociception.

Table 62-1 specifies important pain categories commonly treated (somatic, visceral, and neuropathic) and defines the elements and characteristics of nociception, the peripheral physiologic aspect of pain perception (Fig. 62-1). *Nociception* refers to how specialized fibers (largely, but not exclusively, the small unmyelinated A-delta and C fibers) in the peripheral nervous system transmit nerve impulses (usually transmitting signals originating from peripheral mechano- and chemoreceptors) through synapses in the spinal cord's dorsal horn through (but not exclusively through) the spinothalamic tracts to the brain's higher centers, where nociception is converted to pain, with all of its cognitive and emotional ramifications.

THE ASSESSMENT AND MEASUREMENT OF PAIN IN CHILDREN

Whenever feasible, the physician should ask the patient about the character, location, quality, duration, frequency, and intensity of the pain. Some children may not report pain because of fears (often well-founded) of talking to strangers, disappointing or bothering others, receiving an injection if they report pain, returning to the hospital if they admit to pain, and other negative possible reactions. For infants and nonverbal children, their parents, pediatricians, nurses, and other caregivers are constantly challenged to interpret whether the children's distressed behaviors represent pain, fear, hunger, or a range of other perceptions or emotions. Therapeutic trials of comfort measures (cuddling, feeding) and analgesic medications may be helpful in clarifying the triggers of the behaviors.

Behavior and physiologic signs are useful, but they can be misleading. A toddler may scream and grimace during an ear examination because of fear rather than pain. Conversely, children with inadequately relieved persistent pain from cancer, sickle cell disease, trauma, or surgery may withdraw from their surroundings and appear very quiet, leading observers to conclude falsely that they are comfortable or sedated. In these situations, increased dosing of analgesics may make the child become more, not less, interactive and alert. Similarly, neonates and young infants may close their eyes, furrow their brows, and clench their fists in response to pain. Adequate analgesia is often associated with eye opening and increased involvement in the surroundings. A child who is experiencing significant chronic pain may play normally as a way to distract attention away from pain. This coping behavior is sometimes misinterpreted as evidence of the child's "faking" or exaggerating pain at other times.

Age-Specific and Developmentally Specific Measures

Because infants, young children, and nonverbal children cannot express the quantity of pain they experience, several pain scales have been devised in an attempt to quantify pain in these populations (Fig. 62-2; Table 62-2).

The Newborn and Infant

There are several behavioral distress scales for the infant and young child, mostly emphasizing the patient's facial expressions, crying, and body movement. Facial expression measures appear most useful and specific in neonates. Autonomic and vital signs can indicate pain, but because they are nonspecific, they may reflect other processes, including fever, hypoxemia, and cardiac or renal dysfunction.

The Older Child

Children ages 3-7 yr become increasingly articulate in describing the intensity, location, and quality of pain. Pain is occasionally referred to adjacent areas; referral of hip pain to the leg or knee is common in this age range. Self-report measures for children this age include using drawings, pictures of faces, or graded color intensities. Children age 8 yr and older can usually use verbal numerical rating scales or visual analog pain scales accurately (see Fig. 62-2). Verbal numerical ratings are preferred and considered the gold standard; valid and reliable ratings can be obtained from children 8 yr and older. The Numerical

Rating Scale consists of numbers from 0-10, in which 0 represents no pain and 10 represents very severe pain. There is debate about the label for the highest pain rating, but the current agreement is *not* to use the term "worst pain possible," because children can always imagine a greater pain. In the United States, regularly documented pain assessments are required for hospitalized children and children attending outpatient hospital clinics and emergency departments. Pain scores do not always correlate with changes in heart rate or blood pressure.

The Cognitively Impaired Child

Measuring pain in cognitively impaired children remains a challenge. Understanding pain expression and experience in this population is important, because behaviors may be misinterpreted as indicating that cognitively impaired children are more insensitive to pain than cognitively competent children. Children with trisomy 21 may express pain less precisely and more slowly than the general population. Pain in children with autism spectrum disorders may be difficult to assess because these children may be both *hyposensitive* and *hypersensitive* to many different types of sensory stimuli, and they may have limited communication abilities. Although self-reports of pain can be elicited from some children who are cognitively impaired, observational measures have better validation among these children. The Noncommunicating Child's Pain Checklist—Postoperative Version is recommended for children up to 18 yr. Maladaptive behaviors and reduction in functions may also indicate pain. Children with severe cognitive impairments frequently experience pain.

A CONCEPTUAL FRAMEWORK FOR THE TREATMENT OF PEDIATRIC PAIN

A number of models have been developed to understand the various factors that influence children's pain. Many of these theories focus on factors that explain the interindividual variability in pain perception, and the chronicity and impairment experienced with pain. Central to these models are interrelationships among biologic, cognitive, affective, and social factors that influence children's pain and disability, commonly referred to as biopsychosocial models of pain. Biologic factors include the child's physical health, central nervous system factors (pain processing), sex, pubertal status, and genetic factors.

Table 62-1 Pain Categories and Characteristics

PAIN CATEGORY	DEFINITION AND EXAMPLES	CHARACTERISTICS
Somatic	Pain resulting from injury to or inflammation of tissues (skin, muscle, tendons, bone, joints, fascia, vasculature, etc.) *Examples:* burns, lacerations, fractures, infections, inflammatory conditions	*In skin and superficial structures:* sharp; pulsatile; well-localized *In deep somatic structures:* dull; aching; pulsatile; not well-localized
Visceral	Pain resulting from injury to or inflammation of viscera *Examples:* angina, hepatitic distention, bowel distention or hypermobility, pancreatitis	Aching and cramping; nonpulsatile; poorly localized (e.g., appendiceal pain perceived around umbilicus) or referred to distant locations (e.g., angina perceived in shoulder)
Neuropathic	Pain resulting from injury to, inflammation of, or dysfunction of the peripheral or central nervous systems. *Examples:* complex regional pain syndrome, phantom limb pain, Guillain-Barré syndrome, sciatica	Spontaneous; burning; lancinating or shooting; dysesthesias (pins and needles, electrical sensations); hyperalgesia (amplification of noxious stimuli); hyperpathia (widespread pain in response to a discrete noxious stimulus); allodynia (pain in response to nonpainful stimulation); pain may be perceived distal or proximal to site of injury, usually corresponding to innervation pathways (e.g., sciatica)

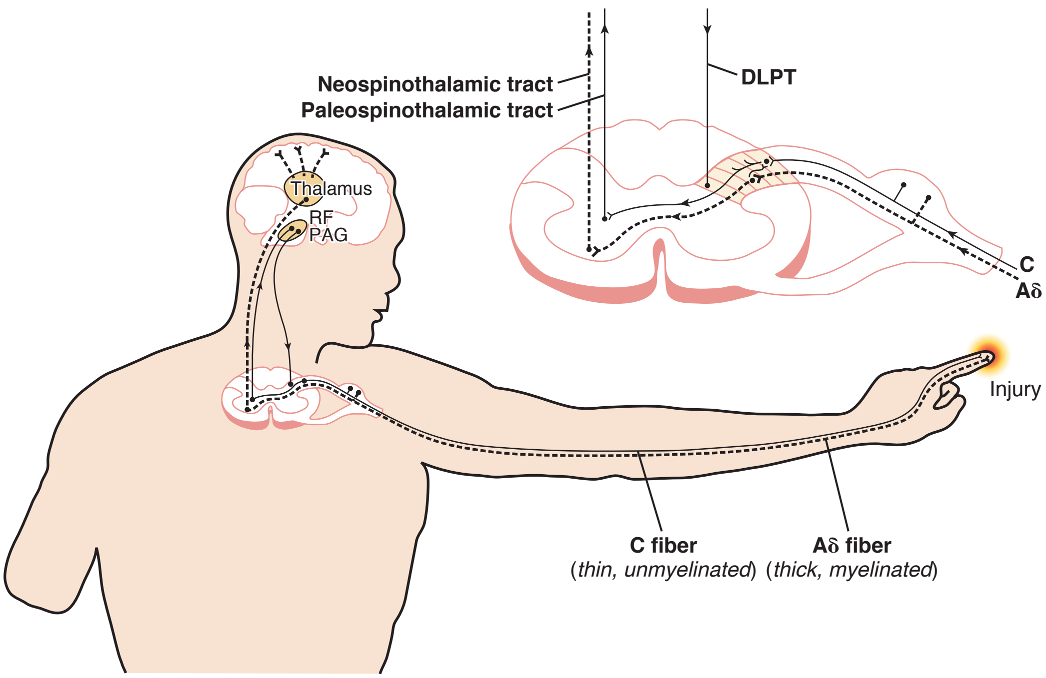

Figure 62-1 The typical neural pathways of nociception, also showing higher projection of nociception to the cortex, where the sensation of nociception is translated to the conscious and emotional phenomenon of pain. *DLPT,* dorsolateral pontine tegmentum; *PAG,* periaqueductal gray; *RF,* reticular formation.

Behavioral Indicators

Facial grimacing: The Neonatal Facial Coding System* uses several facial actions that may be indicators of pain. Pain is characterized by a bulging brow with tight creases in between; tightly closed eyelids; a deeply furrowed nasolabial groove; a horizontal, wide opened mouth; and a taut tongue that may be quivering along with the chin.

Crying: May be an indicator of pain.

Activity: Withdrawal or immobilization of a limb may be an indicator of pain.

Response to comfort measures: Feeding, swaddling, holding, and ensuring that the infant is neither wet nor cold may help to discriminate between pain and other conditions.

Physiologic indicators: Alterations in heart rate, blood pressure, SpO_2, respiratory rate, or alterations in pattern of respiration may be nonspecific indicators of pain.

Multidimensional Instrument

FLACC[†] Scoring System: May be used in preverbal, mechanically ventilated, or cognitively impaired patients; it is an acronym that includes five indicators, each scored as a 0, 1, or 2 that forms a ten-point composite scale with a range from "0" (no pain) to "10" (worst pain).

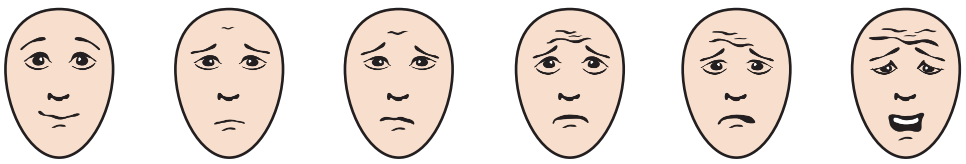
FLACC: Score each category between 0 and 2. The total score may be any number from 0 to 10.

Score:	0	1	2
Face	No expression	Occational action	Frequent action
Legs	Normal	Restless or tense	Kicking, legs withdrawn
Activity	Quiet	Shifting or tense	Rigid, arched, jerking
Cry	None	Moan, whimper	Steady crying, screaming, sobbing, or frequent complaints
Consolability	Content	Consolable	Inconsolable

Self-Report of Pain

Categorical description: Toddlers or young children are asked to say if they are having "a little bit," a "middle amount," or "a lot" of pain.

Faces Scales[‡]: Children who do not have an appreciation of ordinal numbering are asked to rate their pain based upon cartoons depicting facial indicators of distress.



0 2 4 6 8 10

NRS[§]: Older children and teenagers are asked to rate their pain on a scale of "0" (no pain) to "10" (worst pain).

VAS[§]: Children or teenagers are asked to move an indicator along a mechanical slide to depict the level of pain; the clinician reads a number along a 10-cm indicator on the back to determine the numeric score.

Figure 62-2 Clinically useful pain assessment tools. *(Adapted from Burg FD, Ingelfinger JR, Polin RA, et al, editors:* Current pediatric therapy, *ed 18, Philadelphia, 2006, WB Saunders, p. 16; and Hicks CL, von Baeyer CL, Spafford P, et al: The Faces Pain Scale—revised: toward a common metric in pediatric pain measurement,* Pain *93:173–183, 2001.)*

Individual child cognitive and affective factors related to perception of pain are anxiety, fear, negative affect, pain behaviors, and functional disability, whereas social factors include such areas as culture, socioeconomic status, school environment, social and peer interactions, and parental and family factors.

A framework that considers the interplay of biologic, psychologic, and social factors is useful for understanding pediatric pain and to guide pain assessment and the delivery of both pharmacologic and nonpharmacologic interventions for pain management. Many simple interventions designed to promote relaxation and patient control can be expected to work synergistically with pain medications for optimal relief of pain and related distress. Moreover, psychologic interventions are often coupled with physical therapy interventions to assist in the management of disabling chronic pain.

Pharmacologic Treatment of Pain

Developmental Pharmacology

The pharmacokinetics and pharmacodynamics of analgesics vary with age; drug responses in infants and young children differ from those in older children and adults. The elimination half-life of most analgesics is prolonged in neonates and young infants because of their immature hepatic enzyme systems and glomerular filtration. Clearance of

Table 62-2 Pain Measurement Tools

NAME	FEATURES	AGE RANGE	ADVANTAGES	VALIDATION AND USES	LIMITATIONS
Visual Analog Scale (VAS)	Horizontal 10-cm line; subject marks a spot on the line between anchors of "no pain" (or neutral face) and "most pain imaginable" (or sad face)	6-8 yr and older	Good psychometric properties; validated for research purposes	Acute pain Surgical pain Chronic pain	Cannot be used in younger children or in those with cognitive limitations Requires language skills and numerical processing; upper anchor of "most pain" requires an experiential reference point that is lacking in many children
Likert Scale	Integers from 0-10, inclusive, corresponding to a range from no pain to most pain	6-8 yr and older	Good psychometric properties; validated for research purposes	Acute pain Surgical pain Chronic pain	Same as for VAS
Faces Scales (e.g., FACES-R, Wong-Baker, Oucher, Bieri, McGrath scales)	Subjects rate their pain by identifying with line drawings of faces or photos of children	4 yr and older	Can be used at younger ages than VAS and Likert	Acute pain Surgical pain	Choice of "no pain" face affects responses (neutral vs smiling); not culturally universal
Behavioral or combined behavioral-physiologic scales (e.g., FLACC, N-PASS, CHEOPS, OPS, FACS, NIPS)	Scoring of observed behaviors (e.g., facial expression, limb movement) ± heart rate and blood pressure	Some work for any ages; some work for specific age groups, including preterm infants	May be used in both infants and nonverbal children	FLACC, N-PASS: Acute pain Surgical pain	Nonspecific; overrates pain in toddlers and preschool children; underrates persistent pain; some measures are convenient, but others require videotaping and complex processing; vital sign changes unrelated to pain can occur and may affect total score
Autonomic measures (e.g., heart rate, blood pressure, heart rate spectral analyses)	Scores changes in heart rate, blood pressure, or measures of heart rate variability (e.g., "vagal tone")	All ages	Can be used at all ages; useful for patients receiving mechanical ventilation		Nonspecific; vital sign changes unrelated to pain may occur, and may artifactually increase or decrease score
Hormonal-metabolic measures	Plasma or salivary sampling of "stress" hormones (e.g., cortisol, epinephrine)	All ages	Can be used at all ages		Nonspecific; changes unrelated to pain can occur; inconvenient; cannot provide "real-time" information; standard normal values not available for every age bracket

analgesics may also be variable in young infants and children. Renal blood flow, glomerular filtration, and tubular secretion increase dramatically in the 1st few weeks, approaching adult values by 3-5 mo of age. Renal clearance of analgesics is often greater in toddlers and preschool-age children than in adults, whereas in premature infants clearance is reduced. Age-related differences in body composition and protein binding also exist. Total-body water as a fraction of body weight is greater in neonates than in children or adults. Tissues with high perfusion, such as the brain and heart, account for a larger proportion of body mass in neonates than do other tissues, such as muscle and fat. Because of decreased serum concentrations of albumin and α_1-acid glycoprotein, neonates have reduced protein binding of some drugs, resulting in higher amounts of free, unbound, pharmacologically active drug.

Acetaminophen, Aspirin, Nonsteroidal Antiinflammatory, and Coxib Drugs

Acetaminophen and nonsteroidal antiinflammatory drugs (NSAIDs) have replaced aspirin as the most commonly used antipyretics and oral, nonopioid analgesics (Table 62-3).

Acetaminophen, a generally safe, nonopioid analgesic and antipyretic, has the advantage of intravenous, rectal, and oral routes of administration. Acetaminophen is not associated with the gastrointestinal or antiplatelet effects of aspirin and NSAIDs, making it a particularly useful drug in patients with cancer. Unlike aspirin and NSAIDs, acetaminophen has only mild antiinflammatory action.

Acetaminophen toxicity can result from either a large single dose or cumulative, excessive dosing over days or weeks (see Chapters 63 and 363). A single, massive overdose overwhelms the normal glucuronidation and sulfation metabolic pathways in the liver, whereas long-term overdosing exhausts supplies of the sulfhydryl donor glutathione, leading to alternative cytochrome P450–catalyzed oxidative metabolism and the production of the hepatotoxic metabolite *N*-acetyl-*p*-benzoquinone imine (NAPQI). Toxicity manifests as fulminant hepatic necrosis and failure in infants, children, and adults. Drug biotransformation processes are immature in neonates, very active in young children, and somewhat less active in adults. Young children are more resistant to acetaminophen-induced hepatotoxicity than are adults as a result of metabolism differences: Sulfation predominates over glucuronidation in young children, leading to a reduction in *N*-acetyl-*p*-benzoquinone imine production.

Aspirin is indicated for certain rheumatologic conditions and for inhibition of platelet adhesiveness, as in the treatment of Kawasaki disease. Concerns about Reye syndrome have resulted in a substantial decline in pediatric aspirin use (see Chapter 357).

The **NSAIDs** are used widely to treat pain and fever in children. NSAIDs are nonselective cyclooxygenase (COX) inhibitors (coxibs), that is, drugs that nonselectively block the activity of both COX-1

Table 62-3 Commonly Used Nonopioid Medications

MEDICATION	DOSAGE	COMMENT(S)
Acetaminophen	10-15 mg/kg PO q4h 10 mg/kg IV q4h 15 mg/kg IV q6h 10 mg/kg IV q6h (<2 yr) 20-30 mg/kg/PR q4h 40 mg/kg/PR q6-8h Maximum daily dosing: 90 mg/kg/24 hr (children) 60 mg/kg/24 hr (<2 yr) 30-45 mg/kg/24 hr (neonates)	Little antiinflammatory action; no antiplatelet or adverse gastric effects; overdosing can produce fulminant hepatic failure
Aspirin	10-15 mg/kg PO q4h Maximum daily dosing: 120 mg/kg/24 hr (children)	Antiinflammatory; prolonged antiplatelet effects; may cause gastritis; associated with Reye syndrome
Ibuprofen	8-10 mg/kg PO q6h	Antiinflammatory; transient antiplatelet effects; may cause gastritis; extensive pediatric safety experience
Naprosyn	5-7 mg/kg PO q8-12h	Antiinflammatory; transient antiplatelet effects; may cause gastritis; more prolonged duration than that of ibuprofen
Ketorolac	Loading dose 0.5 mg/kg, then 0.25-0.3 mg/kg IV q6h to a maximum of 5 days; maximum dose 30 mg loading with maximum dosing of 15 mg q6h	Antiinflammatory; reversible antiplatelet effects; may cause gastritis; useful for short-term situations in which oral dosing is not feasible
Celecoxib	3-6 mg/kg PO q12-24h	Antiinflammatory; no antiplatelet or gastric effects; cross-reactivity with sulfa allergies
Choline magnesium salicylate	10-20 mg/kg PO q8-12h	Weak antiinflammatory; lower risk of bleeding and gastritis than with conventional NSAIDs
Nortriptyline, amitriptyline, desipramine	0.1-0.5 mg/kg PO qhs	For neuropathic pain; facilitates sleep; may enhance opioid effect; may be useful in sickle cell pain; risk of dysrhythmia in prolonged QTc syndrome; may cause fatal dysrhythmia in overdose; FDA says agents may enhance suicidal ideation
Gabapentin	100 mg bid or tid titrated to up to 3,600 mg/24 hr	For neuropathic pain; associated with sedation, dizziness, ataxia, headache, and behavioral changes
Quetiapine, risperidone, chlorpromazine, haloperidol	Quetiapine: 6.25 or 12.5 mg PO qd (hs); may use q6h prn acute agitation with pain. Escalate dose to 25 mg/dose if needed. Risperidone: useful for PDD spectrum or tic disorder and chronic pain; 0.25-1 mg (in 0.25-mg increments) qd or bid; see PDR for other dosing.	Useful when arousal is amplifying pain; often used when patient first starting SSRI and then weaned after at least 2 wk; check for normal QTc before initiating; side effects include extrapyramidal reactions (diphenhydramine may be used to treat) and sedation; in high doses, can lower the seizure threshold
Fluoxetine	10-20 mg PO qd (usually in morning)	SSRI for children with anxiety disorders in which arousal amplifies sensory signaling; useful in PDD spectrum disorders in very low doses; best to use in conjunction with psychiatric evaluation
Sucrose solution via pacifier or gloved finger	*Preterm infants (gestational age):* 28 wk: 0.2 mL swabbed into mouth 28-32 wk: 0.2-2 mL, depending on suck/swallow >32 wk: 2 mL *Term infants:* 1.5-2 mL PO over 2 min	Allow 2 min before starting procedure; analgesia may last up to 8 min; the dose may be repeated once

FDA, U.S. Food and Drug Administration; IV, intravenous(ly): NSAIDs, nonsteroidal antiinflammatory drugs; PDD, pervasive developmental disorder; PDR, *Physicians' Desk Reference;* PR, per rectum; QTc, corrected QT interval on an electrocardiogram; SSRI, selective serotonin reuptake inhibitor.

(found in gastric mucosa and platelets) and COX-2 (active in inflammatory pathways and cortical renal blood flow regulation) enzymes that synthesize prostaglandins. In children with juvenile idiopathic arthritis, ibuprofen and aspirin are equally effective, but ibuprofen is associated with fewer side effects and better drug adherence. NSAIDs and coxibs used adjunctively in surgical patients reduce opioid requirements (and, therefore, opioid side effects) by as much as 35-40%. Although NSAIDs can be useful postoperatively, they should be used as an adjunct to, not as a substitute for, opioids in patients with moderate to severe pain.

Ketorolac, an IV or intranasal NSAID, is useful in treating moderate to severe acute pain in patients who are unable or unwilling to swallow oral NSAIDs. Intravenous ibuprofen is approved in the United States for the management of pain and fever for 5 days or fewer, although there is no pediatric indication in the package labeling. In Europe, IV ibuprofen is used to treat pediatric pain.

Adverse effects of NSAIDs are uncommon, but they may be serious when they occur. They include inhibition of bone growth and healing; gastritis with pain and bleeding; decreased renal blood flow that may reduce glomerular filtration and enhance sodium reabsorption, in some cases leading to tubular necrosis; hepatic dysfunction and liver failure; inhibition of platelet function; and an increased incidence of cardiovascular events in patients predisposed to stroke and myocardial infarction. Although the overall incidence of bleeding is very low, gastric bleeding is the most common cause of mortality related to this class of analgesics.

NSAIDs should not be used in the child with a bleeding diathesis or at risk for bleeding or when surgical hemostasis is a concern, such as after tonsillectomy. The drug class is usually avoided in the setting of bone healing, except perhaps in the 1st few days following surgery.

Renal injury from short-term use of ibuprofen in euvolemic children is quite rare; the risk is increased by hypovolemia or cardiac

dysfunction. The safety of both ibuprofen and acetaminophen for short-term use is well established (see Table 62-3).

Coxib drugs available in the United States are limited to oral celecoxib, whereas in Europe and elsewhere parenteral parecoxib and oral rofecoxib are available (parecoxib was not approved for use in the United States, while rofecoxib was approved and withdrawn from the market because of concern of enhancement of the risk of heart attacks and stroke, which was subsequently found to be associated with all the coxibs and NSAID drugs as well). The coxib drugs are selective COX-2 enzyme inhibitors; therefore they are effective antiinflammatory and analgesic molecules that generally do not result in platelet inhibition and bleeding or in gastric inflammation or ulceration, findings that may be seen with the nonselective COX inhibitors in the NSAID class. However, coxib drugs do inhibit regulation of cortical renal blood flow, and therefore carry the same risk of renal dysfunction and acute tubular necrosis. Celecoxib is therefore an appropriate primary or adjunctive analgesic to use in children following surgery, children with gastric mucosal pathology, or oncology patients in whom concern for hemostasis contraindicates conventional NSAIDs.

Opioids

Opioids are analgesic substances either derived from the opium poppy (opiates) or synthesized to have a similar chemical structure and mechanism of action (opioids). The older, pejorative term narcotics should not be used for these agents, because it connotes criminality and lacks pharmacologic descriptive specificity. Opioids are administered for moderate and severe pain, such as acute postoperative pain, sickle cell crisis pain, and cancer pain. Opioids can be administered by the oral, rectal, oral transmucosal, transdermal, intranasal, IV, epidural, intrathecal, subcutaneous, or intramuscular route. Historically, infants and young children have been underdosed with opioids for fear of significant respiratory side effects. In contrast, the use of opioids for moderate-to-severe noncancer pain does not have the evidence base that their use in cancer-associated pain does. There is concern for the potential for unwarranted use of opioids to increase the incidence of side effects. With proper understanding of the pharmacokinetic and pharmacodynamics of opioids, children can receive effective relief of pain and suffering with a good margin of safety (Tables 62-4 to 62-7).

Opioids act by mimicking the actions of endogenous opioid peptides, binding to receptors in the brain, brainstem, spinal cord, and peripheral nervous system, and thus leading to inhibition of nociception. Opioids have dose-dependent respiratory depressant effects, and they blunt ventilatory responses to hypoxia and hypercarbia. These respiratory depressant effects can be increased with coadministration of other sedating drugs, such as benzodiazepines or barbiturates. What was once thought to represent infants' particular sensitivity to the opioids' respiratory depressant effects we now understand to be a result of infants' lower metabolic clearance of opioids and higher blood levels with frequent dosing.

Optimal use of opioids requires proactive and anticipatory management of side effects (see Table 62-6). Common side effects include constipation, nausea, vomiting, urinary retention, and pruritus. The most common, troubling, but treatable side effect is constipation. Stool softeners and stimulant laxatives should be administered to most patients receiving opioids for more than a few days. Constipation also remains a problem with long-term opioid administration. A peripherally acting opiate μ-receptor antagonist, methylnaltrexone, promptly and effectively reverses opioid-induced constipation in patients with chronic pain who are receiving opioids daily. In addition lubiprostone, an epithelial chloride channel agent, has been approved for the treatment of opioid-induced constipation in adults with chronic noncancer pain. The side effect of nausea typically subsides with long-term dosing, but it may require treatment with antiemetics, such as a phenothiazine, butyrophenones, antihistamines, or a serotonin receptor antagonist such as ondansetron or granisetron. Pruritus and other complications during patient-controlled analgesia (PCA) with opioids may be effectively managed by low-dose IV naloxone (see Table 62-6).

One of the potent barriers to effective management of pain with opioids is the unrealistic fear of addiction held by many prescribing

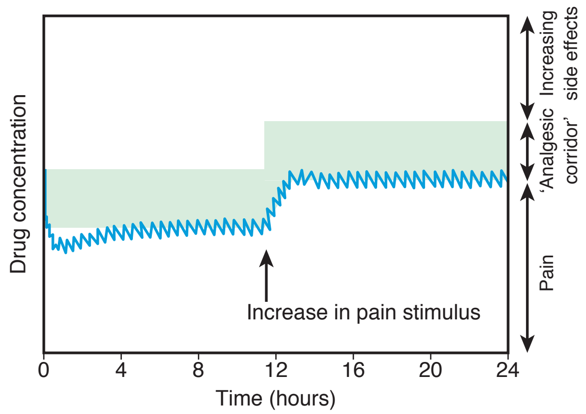


Figure 62-3 Patient-controlled analgesia is more likely to keep blood concentrations of opioid within the "analgesic corridor" and allows rapid titration if there is an increase in pain stimulus requiring higher blood levels of opioid to maintain the analgesia. *(From Burg FD, Ingelfinger JR, Polin RA, et al, editors:* Current pediatric therapy, *ed 18. Philadelphia, 2006, WB Saunders, p. 16.)*

pediatricians and parents. Pediatricians should understand the phenomena of tolerance, dependence, withdrawal, and addiction (see Table 62-5) and should know that the rational short- or long-term use of opioids in children does not lead to a predilection or risk of addiction in a child not otherwise at risk by virtue of genetic background and social milieu. It is important for pediatricians to realize that even patients with recognized substance-abuse diagnoses are entitled to effective analgesic management, which often includes the use of opioids. When there are legitimate concerns about addiction in a patient, then safe, effective opioid pain management is often best managed by specialists in pain management and/or addiction medicine.

There is no longer a reason to administer opioids by intramuscular injection. Continuous IV infusion of opioids is an effective option that permits more constant plasma concentrations and clinical effects than intermittent IV bolus dosing, without the pain associated with intramuscular injection. The most common approach in pediatric centers is to administer a low-dose basal opioid infusion, while permitting patients to use a patient-controlled analgesia (PCA) device to titrate the dosage above the infusion (see Chapter 61; Fig. 62-3). Compared with children given intermittent intramuscular morphine, children using PCA reported better pain scores. PCA has several other advantages: (1) dosing can be adjusted to account for individual pharmacokinetic and pharmacodynamic variation and for changing pain intensity during the day; (2) psychologically, the patient is more in control, actively coping with the pain; (3) overall opioid consumption is lower; (4) fewer side effects occur; and (5) patient satisfaction is generally much higher. Children as young as 5-6 yr can effectively use PCA. The device can be activated by parents or nurses—the latter practice known as PCA-by-proxy; PCA-by-proxy produces analgesia in a safe, effective manner for children who cannot activate the PCA demand button themselves because they are too young or intellectually or physically impaired. PCA overdoses occur when well-meaning, inadequately instructed parents pushed the PCA button in medically complicated situations with or without the use of PCA-by-proxy, highlighting the need for patient and family education, the use of protocols, and adequate nursing supervision.

Local Anesthetics

Local anesthetics are widely used in children for topical application, cutaneous infiltration, peripheral nerve block, epidural neuraxial blocks, intrathecal infusions, and IV infusions (see Chapter 61; Table 62-8). Local anesthetics can be used with excellent safety and effectiveness. Local anesthetics interfere with neural transmission by blocking sodium channels. Excessive systemic dosing can cause seizures, central nervous system (CNS) depression, and by cardiac and arteriolar sodium channel blockade hypotension, arrhythmias, cardiac

Table 62-4 Pediatric Dosage Guidelines for Opioid Analgesics

DRUG	EQUIANALGESIC DOSES		PARENTERAL DOSING (WEIGHT)		IV:PO DOSE RATIO	ORAL DOSING (WEIGHT)		COMMENTS
	IV	ORAL	<50 kg	>50 kg		<50 kg	>50 kg	
Fentanyl	10 µg	100 µg	0.5-1 µg/kg q1-2h 0.5-1.5 µg/kg/hr	0.5-1 µg/kg q1-2h 0.5-1.5 µg/kg/hr	Oral transmucosal: 1:10 Transdermal: 1:1	Oral transmucosal: 10 µg/kg Transdermal: 12.5-50 µg/hr	Transdermal patches available; patch reaches steady state at 24 hr and should be changed q72h	70-100 times as potent as morphine with rapid onset and shorter duration With high doses and rapid administration, can cause chest-wall rigidity Useful for short procedures; transdermal form should be used only in opioid-tolerant patients with chronic pain
Hydrocodone	N/A	1.5 mg	N/A	N/A	N/A	0.15 mg/kg	10 mg	Weak opioid; only available in form with acetaminophen
Hydromorphone	0.2 mg	0.6 mg	0.01 mg q2-4h 0.002 mg/kg/hr	0.01 mg q2-4h 0.002 mg/kg/hr	1:3	0.04-0.08 mg/kg q3-4h	2-4 mg q3-4h	5× the potency of morphine; no histamine release and fewer adverse events than morphine
Meperidine	10 mg	30 mg	0.5 mg/kg q2-4h	0.5 mg/kg q2-4h	1:4	2-3 mg/kg q3-4h	100-150 mg q3-4h	Primary use in low doses is for treatment of rigors and shivering after anesthesia or with amphotericin or blood products Not appropriate for repeated dosing
Methadone	1 mg	2 mg	0.1 mg/kg q8-24h	0.1 mg/kg q8-24h	1:2	0.2 mg/kg q8-12h PO; available as liquid or tablet	2.5 mg tid	Duration 12-24 hr; useful in certain types of chronic pain; requires additional vigilance, because it will accumulate over 72 hr and produce delayed sedation When patients who are tolerant to opioids are switched to methadone, they show incomplete cross-tolerance and improved efficacy; because it is associated with prolonged QTc, monitoring is needed for children on high and extended dosing
Morphine	1 mg	3 mg	0.05 mg/kg q2-4h 0.01-0.03 mg/kg/hr	*Bolus:* 5-8 mg q2-4h	1:3	Immediate release: 0.3 mg/kg q3-4h Sustained release: 20-35 kg: 10-15 mg q8-12h 35-50 kg: 15-30 mg q8-12h	Immediate release: 15-20 mg q3-4h Sustained release: 30-90 mg q8-12h	Potent opioid for moderate/severe pain; may cause histamine release Sustained-release form must be swallowed whole; if crushed, becomes immediate-acting, leading to acute overdose
Oxycodone	N/A	3 mg	N/A	N/A	N/A	0.1-0.2 mg q3-4h; available in liquid (1 mg/mL)	Immediate release: 5-10 mg q4h Sustained release: 10-120 mg q8-12h	Strong opioid only available as an oral agent in North America; more potent than and preferable to hydrocodone Sustained-release form must be swallowed whole; if crushed, becomes immediate-acting, leading to acute overdose

N/A, not available.

Table 62-5 Practical Aspects of Prescribing Opioids

- Morphine, hydromorphone, or fentanyl is regarded as first choice for severe pain.
- Dosing should be titrated and individualized. There is no "right" dose for everyone.
- The right dose is the dose that relieves pain with a good margin of safety.
- Dosing should be more cautious in infants, in patients with coexisting diseases that increase risk or impair drug clearance, and with concomitant administration of sedatives.
- Anticipate and treat peripheral side effects, including constipation, nausea, and itching.
- Give doses at sufficient frequency to prevent the return of severe pain before the next dose.
- Use a drug delivery method, such as patient-controlled anesthesia or continuous infusions that avoid the need for "prn" decision making.
- With opioid dosing for more than 1 wk, taper gradually to avoid abstinence syndrome.
- When converting between parenteral and oral opioid doses, use appropriate potency ratios (see Table 62-4).
- *Tolerance* refers to decreasing drug effect with continued administration of a drug. Over time a patient will need higher dosing to achieve the same clinical effect; however, tolerance to sedation and respiratory depression develop more rapidly than tolerance to analgesia. Thus, with higher doses, patients do not experience oversedation or respiratory depression.
- *Dependence* refers to the need for continued drug dosing to prevent abstinence syndrome when a drug is abruptly discontinued or its dose reduced. Abstinence syndrome is characterized by irritability, agitation, autonomic arousal, nasal congestion, piloerection, diarrhea and/or jitteriness, and yawning; it is produced by administration of potent opioids for >5-7 days.
- *Addiction,* a psychiatric pathology, refers to psychologic craving, compulsive drug-seeking behavior, and drug use despite medical harm. Addiction has strong genetic determinants. Opioid therapy does not lead to addiction in nonsusceptible individuals, nor does opioid underdosing prevent addiction; it may in fact increase drug-seeking behavior for relief of pain (such as watching the clock), referred to as "pseudoaddiction."

Table 62-6 Management of Opioid-Induced Adverse Effects

Respiratory depression	*Naloxone:* 0.01-0.02 mg/kg up to a full reversal dose of 0.1 mg/kg. May be given IV, IM, subcutaneously (SC), or via endotracheal tube (ET). The full reversal dose should initially be used for apnea in opioid-naïve patients. In opioid-tolerant patients, a reduced dose should be given and titrated up slowly to treat symptoms but prevent acute withdrawal. Ventilation may need to be supported during this process. Dose may be repeated every 2 min to a total of 10 mg. Adult maximum dose is 2 mg/dose. Give with caution to patients who are receiving long-term opioid therapy, as it may precipitate acute withdrawal. Duration of effect is 1-4 hr; therefore, close observation for renarcotization is essential.
Excessive sedation without evidence of respiratory depression	*Methylphenidate**: 0.3 mg/kg per dose PO (typically 10-20 mg/dose to a teenager) before breakfast and lunch. Do not administer to patients receiving clonidine, because dysrhythmias may develop. *Dextroamphetamine*: 2.5-10 mg on awakening and at noon. Not for use in young children or in patients with cardiovascular disease or hypertension. *Modafinil:* Pediatric dose not established. May be useful in selected patients. Typical adult dose: 50-200 mg/day. Change opioid or decrease the dose.
Nausea and vomiting	*Metoclopramide*†*:* 0.15 mg/kg IV up to 10 mg/dose q6-12h for 24 hr. *Trimethobenzamide:* PO or rectally (PR) if weight <15 kg, 100 mg q6h; if >15 kg, 200 mg q6h. (Note: Suppository contains benzocaine 2%.) Not for use in newborn infants or premature infants. 5-HT_3 blockers: *Ondansetron:* 0.15 mg/kg up to 8 mg IV q6-8h not to exceed 32 mg/day (also available as a sublingual tablet). *Granisetron:* 10-20 μg/kg IV q12-24h. *Prochlorperazine** (Compazine): >2 yr or >20 kg, 0.1 mg/kg per dose q8h IM or PO up to 10 mg/dose. Change opioid.
Pruritus	*Hydroxyzine*: 0.5 mg/kg PO q6h. *Nalbuphine:* 0.1 mg/kg IV q6h for pruritus caused by intraaxial opioids, especially fentanyl. Administer slowly over 15-20 min. May cause acute reversal of systemic μ-receptor effects and leave κ-agonism intact. *Naloxone:* 0.003-0.1 mg/kg/hr IV infusion (titrate up to decrease pruritus and reduce infusion if pain increases). *Ondansetron:* 0.05-0.1 mg/kg IV or PO q8h. *Cyproheptadine*†*:* 0.1-0.2 mg/kg PO q8-12h. Maximum dose 12 mg. Change opioid.
Constipation	Encourage water consumption, high-fiber diet, and vegetable roughage. *Bulk laxatives:* Metamucil, Maltsupex. *Lubricants:* Mineral oil 15-30 mL PO qd as needed (not for use in infants because of aspiration risk). *Surfactants:* Sodium docusate (Colace): <3 yr: 10 mg PO q8h 3-6 yr: 15 mg PO q8h 6-12 yr: 50 mg PO q8h >12 yr: 100 mg PO q8h *Stimulants:* Bisacodyl suppository (Dulcolax): <2 yr: 5 mg PR qhs >2 yr: 10 mg PR qhs *Senna syrup* (218 mg/5 mL): >3 yr, 5 mL qhs. *Enema:* Fleet's hypertonic phosphate enema (older children; risk of hyperphosphatemia). *Electrolytic/osmotic:* Milk of magnesia; for severe impaction: polyethylene glycol (GoLYTELY, MiraLAX).
Urinary retention	Straight catheterization, indwelling catheter.

*Avoid in patients taking monoamine oxidase inhibitors.
†May be associated with extrapyramidal side effects, which may be more commonly seen in children than in adults.

Table 62-7 Equianalgesic Doses and Half-Lives ($T_{1/2\beta}$) of Some Commonly Used Opioids

OPIOID	IM/IV DOSE (mg)	ORAL DOSE (mg)	$T_{1/2\beta}$ (hr)
Morphine	10	30	2-3
Meperidine	100	400	3-4
Oxycodone	15	20-30	2-3
Fentanyl	0.15-0.2	—	3-5
Alfentanil	0.75-1.5	—	1-2
Sufentanil	0.02	—	2-3
Diamorphine	5	60	0.5*
Methadone	10	10-15	15-40
Hydromorphone	1.5	7.5	3-4
Tramadol†	100	100	5-7
Buprenorphine	0.4	0.8 (sublingual)	3-5
Pentazocine	60	150	3-5
Nalbuphine	10-20	—	2-4
Butorphanol	2	—	2-3

NOTES:
- Published reports vary in the suggested doses considered to be equianalgesic to morphine. Therefore, titration to clinical response in each patient is necessary.
- Suggested doses are the results of single-dose studies only. Therefore, use of the data to calculate total daily dose requirements and repeated or continuous doses may not be appropriate.
- There may be incomplete cross-tolerance between these drugs. In patients who have been receiving 1 opioid for a prolonged period, it is usually necessary to use a dose lower than the expected equianalgesic dose when changing to another opioid, and to titrate to effect.

*Rapidly hydrolyzed to morphine.
†Only part of its analgesic action results from action on μ opioid receptors.

depression, and cardiovascular collapse. Unlike opioids, local anesthetics therefore require a strict maximum dosing schedule. Pediatricians should be aware of the need to calculate these doses and adhere to guidelines.

Topical local anesthetic preparations do not generally result in measurable systemic blood levels, and can reduce pain in diverse circumstances: suturing of lacerations, placement of peripheral IV catheters, lumbar punctures, and accessing of indwelling central venous ports. The application of tetracaine, epinephrine, and cocaine (TAC) results in good anesthesia for suturing wounds, but TAC should not be used on mucous membranes. Combinations of tetracaine with phenylephrine and lidocaine-epinephrine-tetracaine are equally as effective as TAC, eliminating the need to use a controlled substance (cocaine). EMLA, a topical eutectic mixture of lidocaine and prilocaine used to anesthetize intact skin, is commonly applied for venipuncture, lumbar puncture, and other needle procedures. EMLA is generally safe for use in neonates, but it is associated with prilocaine-induced methemoglobinemia. In circumcision, EMLA is more effective than placebo in providing analgesia, but probably less effective than ring block of the penis. EMLA should be used cautiously for circumcision, because its use may cause redness and blistering on the penis. A small area should be tested for hypersensitivity before EMLA is more widely applied. Lidocaine cream, 5%, has replaced EMLA in many pediatric centers. Lidocaine is the most commonly used local anesthetic for cutaneous infiltration. Maximum safe doses of lidocaine are 5 mg/kg without epinephrine and 7 mg/kg with epinephrine. Although concentrated solutions (2%) are commonly available from hospital pharmacies, more dilute solutions such as 0.25% and 0.5% are as equally as effective as 1-2% solutions. The diluted solutions cause less burning discomfort on injection and permit use of larger volumes without achieving toxic doses. In the surgical setting, cutaneous infiltration is more often performed with bupivacaine 0.25% or ropivacaine 0.2% because of the much longer duration of effect. The maximum dose of these long-acting amide anesthetics is 2-3 mg/kg.

Table 62-9 Examples of Neuropathic Pain Syndromes

PERIPHERAL NERVOUS SYSTEM FOCAL AND MULTIFOCAL LESIONS Postherpetic neuralgia Cranial neuralgias (such as trigeminal neuralgia, glossopharyngeal neuralgia) Diabetic mononeuropathy Nerve entrapment syndromes Plexopathy from malignancy or irradiation Phantom limb pain Posttraumatic neuralgia (such as nerve root compression or after thoracotomy) Ischemic neuropathy
PERIPHERAL NERVOUS SYSTEM GENERALIZED POLYNEUROPATHIES *Metabolic/nutritional:* Diabetes mellitus, pellagra, beriberi, multiple nutritional deficiency, hypothyroidism *Toxic:* Alcohol-, platinum-, or taxane-based chemotherapy, isoniazid, antiretroviral drugs *Infective/autoimmune:* HIV, acute inflammatory polyneuropathy (Guillain-Barré syndrome), neuroborreliosis (Bannwarth syndrome) *Hereditary:* Fabry disease *Malignancy:* Carcinomatosis *Others:* Idiopathic small fiber neuropathy
CENTRAL NERVOUS SYSTEM LESIONS Spinal cord injury Prolapsed disc Stroke (brain infarction, spinal infarction) Multiple sclerosis Surgical lesions (such as rhizotomy, cordotomy) Complex neuropathic disorders Complex regional pain syndrome types I and II

Modified from Freynhagen R, Bennett MI: Diagnosis and management of neuropathic pain, BMJ *339:b3002, 2009.*

Neuropathic pain may respond well to the local application of a lidocaine topical patch (Lidoderm) for 12 hr per day (Table 62-9). *Peripheral neuropathic* pain also may respond to IV lidocaine infusions, which may be used in hospital settings for refractory pain, complex regional pain syndromes, and pain associated with malignancies or the therapy of malignancies, such as oral mucositis following bone marrow transplantation. In these instances, 1-2 mg/kg/hr should be administered, and the infusion titrated to achieve a blood lidocaine level in the 2-5 μg/mL range, with use of twice-daily therapeutic blood monitoring. Table 62-10 lists approaches to *central neuropathic pain*.

Table 62-10 Treatment Recommendations for Central Neuropathic Pain Adapted from Current Evidence-Based Literature

MEDICATION CLASS/DRUG	RECOMMENDED STAGE OF TREATMENT
ANTIDEPRESSANTS	
Tricyclics (amitriptyline, nortriptyline)	1st or 2nd
Serotonin and norepinephrine reuptake inhibitors (duloxetine, venlafaxine)	1st or 2nd
ANTICONVULSANTS	
Pregabalin	1st or 2nd
Gabapentin	1st or 2nd
Lamotrigine	2nd or 3rd (in pain after stroke)
Valproate	3rd
OPIOIDS*	
Levorphanol	
MISCELLANEOUS	
Cannabinoids	2nd (in multiple sclerosis)
Mexiletine	3rd

*2nd or 3rd (no specification).

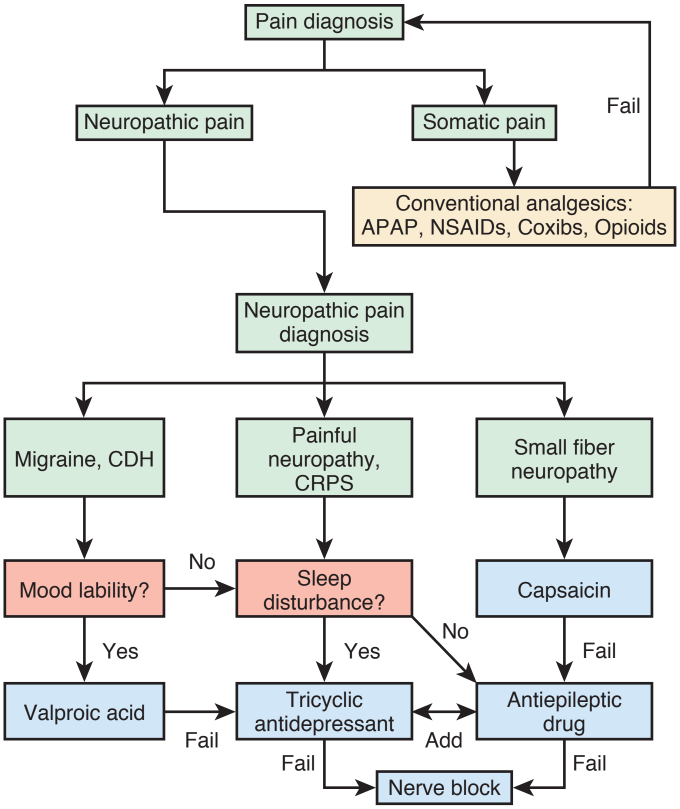

Figure 62-4 A decision tree for the selection of conventional and nonconventional analgesics. *APAP*, acetaminophen; *CDH*, chronic daily headaches; *CRPS*, complex regional pain syndromes; *NSAIDs*, nonsteroidal antiinflammatory drugs.

UNCONVENTIONAL MEDICATIONS IN PEDIATRIC PAIN

Unconventional analgesic medication refers to a wide number of drugs that were developed for other indications but that have been found to have analgesic properties. These drugs include some antidepressants, antiepileptic drugs (AEDs), and neurotropic drugs.

The unconventional analgesics are generally used to manage neuropathic pain conditions, migraine disorders, fibromyalgia syndrome, and some forms of functional chronic abdominal pain syndromes, but they are generally not used to manage surgical, somatic, or musculoskeletal pain. Figure 62-4 presents a decision-making tree that will help the physician select the appropriate analgesic category for various types of pain. The AED gabapentin confers analgesia as well as opioid-sparing benefits following major surgery in adults and in one well-conducted clinical trial in adolescents following spine surgery.

Although several unconventional analgesics have been approved by the FDA for analgesic uses, none has been specifically approved for use in youth with chronic pain. Thus, these drugs should be used with caution, with a focus on mitigating pain to allow a child to participate effectively in therapies and return to normal activity as soon as possible. The use of psychotropic medications should be guided by the principles applied to pharmacologic treatment of any symptom or disease. Target symptoms should be identified, and medication side effects monitored. To determine dosing regimens, the physician should consider the child's weight and the effects that medical condition and other medications, such as psychotropic drugs, may have on the child's metabolism. When available, therapeutic blood-level monitoring should be performed. Side effects should be addressed in detail with both parent and child, and specific instructions given for responding to possible adverse events. It may be necessary to directly address concerns about addiction, dependence, and tolerance in order to decrease treatment-related anxiety and improve medication adherence.

Antidepressant Medications

Antidepressant medications are useful in adults with chronic pain, including neuropathic pain, headaches, and rheumatoid arthritis, independent of their effects on depressive disorders. Antidepressants' analgesic properties inhibit norepinephrine reuptake in the CNS. In children, because clinical trials have been limited, the practitioner should use antidepressants cautiously to treat chronic pain or associated depressive or anxiety symptoms. The FDA issued a "black box warning," its strongest warning, to inform the public of a small but significant increase in suicidal thoughts and attempts in children and adolescents receiving antidepressants. A meta-analysis of studies involving children and adolescents receiving antidepressants indicated that no suicides had been completed. The pediatrician should address this issue with parents of patients being treated with antidepressants and should develop monitoring plans consistent with current FDA recommendations.

Tricyclic Antidepressants

Tricyclic antidepressants (TCAs), which have been studied most in children with chronic pain, are effective in pain relief for symptoms including neuropathic pain, functional abdominal pain, and migraine. The efficacy of TCAs may be based on inhibition of the neurochemical pathways involved in norepinephrine and serotonin reuptake and their interference with other neurochemicals involved in the perception or neural conduction of pain. Because sedation is the most common side effect of TCAs, these medications are also effective in treating the sleep disorders that frequently accompany pediatric pain. Biotransformation of TCAs is extensive in healthy children, so the child should be started on a bedtime dose, which may be able to then be titrated to a daily divided dose, with the larger dose given at bedtime. However, TCAs typically are administered only at bedtime. Pain symptoms usually remit at lower doses than those recommended or required for the treatment of mood disorders. Most children and adolescents do not require more than 0.25-0.5 mg/kg of amitriptyline or nortriptyline once a day at bedtime.

Attention should also be paid to hepatic microsomal enzyme metabolism, because CYP2D6 inhibitors, such as cimetidine and quinidine, can increase levels of TCAs. Anticholinergic side effects, which are remarkably uncommon in children in comparison with adults, often remit over time. Constipation, orthostatic hypotension, and

dental caries from dry mouth should be addressed by emphasizing the importance of hydration and oral hygiene. Other side effects include weight gain, mild bone marrow suppression, and liver dysfunction. Some practitioners recommend monitoring complete blood count and liver function values at baseline and periodically during therapy. TCA blood levels can be obtained as well, but pursuit of therapeutic blood monitoring generally should be decided on an individual basis, particularly if adherence, overdose, or sudden changes in mental status are an issue.

All TCAs inhibit cardiac conduction pathways and prolong the QT interval. Sudden cardiac death is reported in children taking TCAs, principally desipramine, probably related to QTc prolongation. There is no general agreement for monitoring the electrophysiologic effects of these drugs, but it is prudent to obtain a careful personal and family history focusing on cardiac arrhythmias, heart disease, and syncope before the initiation of treatment. If personal or family history is positive for any of these conditions, a baseline electrocardiogram should be obtained, with care taken to ensure that the QTc is <445 msec. We recommend that if the dose of amitriptyline or nortriptyline is increased beyond 0.25-0.5 mg/kg/day, an electrocardiogram should be performed for each dosing increase. With TCAs as with other antidepressants, physical dependence and a known discontinuation syndrome can occur. The discontinuation syndrome includes agitation, sleep disturbances, appetite changes, and gastrointestinal symptoms. These medications should be tapered slowly to assist in distinguishing among symptoms that indicate rebound, withdrawal, or the need for continuing the medication.

Serotonin and Serotonin-Norepinephrine Reuptake Inhibitors

Selective serotonin reuptake inhibitors (SSRIs) have minimal efficacy in the treatment of a variety of pain syndromes in adults. SSRIs are very useful when symptoms of depression or anxiety disorders are present and cannot be addressed adequately by nonpharmacologic means. Although many SSRIs are used in practice with children, only fluoxetine has been approved by the FDA for use in children and adolescents. SSRIs have a significantly milder side-effect profile than do TCAs (most side effects of both are transient), and they have no anticholinergic side effects. Chief side effects include gastrointestinal symptoms, headaches, agitation, insomnia, sexual dysfunction, and anxiety. Rarely, hyponatremia, or the syndrome of inappropriate antidiuretic hormone secretion, may occur. Interactions with other medications that have serotonergic effects (tramadol, trazodone, tryptophan, and triptan migraine medication) may also occur. When these medications are used in combination, there is increased likelihood that a life-threatening **serotonergic syndrome** may occur, with associated symptoms of myoclonus, hyperreflexia, autonomic instability, muscle rigidity, and delirium. There is also a **discontinuation syndrome** associated with shorter-acting SSRIs (paroxetine), which includes dizziness, lethargy, paresthesias, irritability, and vivid dreams. Dosages of medications should be tapered slowly over several weeks.

The selective serotonin-norepinephrine reuptake inhibitors duloxetine and venlafaxine demonstrate significant efficacy with chronic neuropathic and other pain syndromes because they inhibit both serotonin and norepinephrine reuptake, and they may directly block associated pain receptors as well. Venlafaxine has no pain indication labeling, but duloxetine is FDA approved for managing neuropathic pain (diabetic neuropathy) and fibromyalgia syndrome.

Because both SSRIs and selective serotonin-norepinephrine reuptake inhibitors have fewer anticholinergic side effects than TCAs, adherence to them is better than in psychiatric populations taking TCAs. Side effects of both types of drugs include gastrointestinal symptoms, hyperhidrosis, dizziness, and agitation, but these effects generally wane over time. Hypertension and orthostatic hypotension may occur; in addition, the patient's blood pressure should be closely followed, and appropriate hydration should be stressed. Note that whereas appetite stimulation and weight gain are associated with all TCAs, duloxetine is often associated with weight loss, frequently a desirable side effect, especially in weight-conscious adolescent females.

Antiepileptic Drugs

Traditional anticonvulsants, such as carbamazepine and valproic acid, are believed to relieve chronic pain by blocking sodium (valproate and the gabapentinoids) or calcium channels (carbamazepine and oxcarbazepine) at the cellular neuronal level, thereby suppressing spontaneous electrical activity and restoring the normal threshold to depolarization of hypersensitive nociceptive neurons, without affecting normal nerve conduction. These medications are particularly useful in patients with mood disorders and neuropathic pain. In adults, the FDA has approved carbamazepine for trigeminal neuralgia and valproate for migraine prophylaxis, and pregabalin is approved in adults for neuropathic pain complicating diabetes, zoster, and for management of fibromyalgia. Anticonvulsant medications generally have gastrointestinal side effects in addition to sedation, anemia, ataxia, rash, and hepatotoxicity. Carbamazepine and oxcarbazepine are associated with an increased incidence of Stevens-Johnson syndrome. Liver function values and a complete blood count should be obtained at start of therapy (baseline) and monitored with use of both these agents. These medications have narrow therapeutic windows and may have extreme variability in therapeutic blood medication levels, as well as multiple drug–drug interactions; also, they may produce liver disease and renal impairment. Drug levels should be measured with each dose increase and periodically thereafter. Carbamazepine, in particular, causes autoinduction of hepatic microsomal enzymes, which can further complicate obtaining a therapeutic medication level. Frequent pregnancy tests are useful in menstruating female adolescents taking valproate, because severe neural tube defects are associated with this medication.

Less-toxic AEDs have supplanted the use of valproate and carbamazepine in patients with pain. These agents have their own, sometimes troubling side effect profiles, but they are far less toxic than their predecessors and they do not require monitoring of liver function, bone marrow function, or therapeutic blood levels. They are also far less lethal in accidental or deliberate overdose.

Gabapentin, the most widely prescribed AED for the management of pain disorders, demonstrates efficacy in treating children with chronic pain, particularly neuropathic pain, and is playing an increasing role in the management of routine surgical pain. Gabapentin has proven effective in treating chronic headache disorders, and many neuropathic pain syndromes including complex regional pain syndromes, chemotherapy induced neuropathy, postherpetic neuralgia, and diabetic neuropathy in both children and adults. This agent has a relatively benign side-effect profile and few drug interactions. Side effects include somnolence, dizziness, and ataxia. Children occasionally demonstrate side effects not reported in adults—severe impulsive or oppositional behavior, agitation, and, occasionally, depression. These side effects do not seem to be dose related.

A molecularly similar AED, **pregabalin**, works by mechanisms similar to those of gabapentin but appears to have a better side-effect profile. Because it undergoes virtually no hepatic metabolism, pregabalin has no significant drug–drug interactions, a concern in patients with chronic pain, who frequently take multiple medications—for both the pain and the underlying medical condition associated with the pain.

Topiramate also demonstrates greater success than traditional anticonvulsants in treating trigeminal neuralgia in adults and in migraine prophylaxis. Topiramate therapy results more frequently in cognitive dysfunction and short-term memory loss compared with gabapentin or pregabalin, and these neurocognitive effects are particularly problematic for school-age children. The pediatrician should also be aware that in female adolescents, topiramate is associated with weight loss, whereas other anticonvulsants are typically associated with significant weight gain.

Benzodiazepines

Children and adolescents with chronic pain may have comorbid psychologic conditions such as depressed mood, sleep disturbances, or anxiety disorders, including generalized anxiety disorder, separation anxiety, posttraumatic stress disorder, and panic attacks. Pervasive developmental disorders are also common in this population.

Psychologic factors can affect a youth's ability to cope with a pain disorder; a conditioned response to pain may be to feel out of control and to lead to increases in anxiety and pain. Conversely, the feeling of helplessness can sensitize the child to increasing amounts of pain, leading the child to perseverate on the pain, think catastrophically, and feel hopeless. Changes in children's normal routines, with a negative impact on participation in valued activities, may further promote hopelessness, resulting in increased pain experiences and development of a depressive disorder.

Benzodiazepines are anxiolytic medications that also have muscle relaxant effects. They are particularly appropriate in acute situations as valuable adjuncts to the management of pain in the hospital setting, because they inhibit painful muscle spasms in surgical patients, but more importantly because they suppress the anxiety that virtually every hospitalized child experiences, anxiety that interferes with restorative sleep and amplifies the child's perception of pain. Benzodiazepines are useful to calm children with anxiety and anticipatory anxiety about planned, painful procedures.

Because dependence, tolerance, and withdrawal may occur with prolonged use, benzodiazepines are generally not recommended for the routine management of *chronic pain*. In concert with psychotherapy, they help control anxiety symptoms that amplify the perception of pain. Infrequently, benzodiazepines may cause behavioral disinhibition, psychosis-like behaviors, or, in large doses, respiratory depression. When dosing these medications, the pediatrician should consider that many benzodiazepines are metabolized by the cytochrome P450 microsomal enzyme system. This issue may be less significant with lorazepam and oxazepam, which undergo 1st-pass hepatic conjugation. Side effects common to benzodiazepines include sedation, ataxia, anemia, increased bronchial secretions, and depressed mood. If a benzodiazepine is administered for more than several consecutive days, the dosage should be slowly tapered over 2 or more weeks; if therapy is abruptly discontinued, autonomic instability, delirium, seizures, and profound insomnia may occur. There are data that suggest that the use of benzodiazepines during hospitalization for serious disease, such as organ transplantation, might increase the risk of development of posttraumatic stress disorder.

Antipsychotics and Major Sedatives

Low doses of antipsychotic medications are often used to address more-severe anxiety and agitation sometimes associated with chronic pain. The use of these medications is controversial because the associated adverse events may be severe. Typical antipsychotics, including thioridazine (Mellaril), haloperidol (Haldol), and chlorpromazine (Thorazine), are associated with a decrease in seizure threshold, agranulocytosis, weight gain, cardiac conduction disturbances, tardive dyskinesia, orthostatic hypotension, hepatic dysfunction, and life-threatening laryngeal dystonia. These side effects are generally less severe with atypical antipsychotics. Because they may still occur, the pediatrician should obtain a baseline electrocardiogram, liver function values, and complete blood count. If the pediatrician is using typical antipsychotics, an inventory of movement disturbances, such as the Abnormal Involuntary Movement Scale test, should be performed at baseline and at every follow-up visit, because movement disorders can worsen with abrupt withdrawal of medications or can become irreversible.

Atypical antipsychotics are generally associated with less-severe side–effect profiles, particularly with regard to side effects such as dyskinesias and dystonias. Use of olanzapine (Zyprexa), which is particularly helpful with insomnia and severe anxiety, requires assessing and monitoring blood levels of glucose, cholesterol, and triglyceride; olanzapine's side effects may include diabetes, hypercholesterolemia, or significant weight gain. The anticholinergic side effects associated with quetiapine (Seroquel) warrant frequent monitoring of blood pressure. Risperidone at doses >6 mg may cause side effects similar to those of typical antipsychotics. Clozapine (Clozaril), which causes increased incidence of life-threatening agranulocytosis, should generally be avoided as a treatment for children and adolescents with chronic pain. Aripiprazole (Abilify) has been used for severe anxiety and/or for treatment-resistant depression. All antipsychotics are associated with the rare, but potentially lethal **neuroleptic malignant syndrome**, which includes severe autonomic instability, muscular rigidity, hyperthermia, catatonia, and altered mental status.

Nonpharmacologic Treatment of Pain

Numerous psychologic and physical treatments for relieving pain, fear, and anxiety as well as enhancing functioning have been a mainstay of pediatric pain treatment and have excellent safety profiles and proven effectiveness. In the area of acute and procedural pain, nonpharmacologic strategies have long been used to help reduce distress in children undergoing medical procedures and surgery. Many of the behavioral methods aim to help children shift attention from pain and alter pain perception (e.g., distraction, hypnosis, imagery). In the treatment of chronic pain, cognitive-behavioral therapies (CBTs) are the most implemented nonpharmacologic treatment. CBT was developed with the goal of modifying social/environmental and behavioral factors that may exacerbate the child's experience of pain and pain-related disability. There are now several decades of research available on CBTs for pediatric chronic pain. Meta-analyses of randomized controlled trials of CBT interventions have found large positive effects of psychologic intervention on pain reduction in children with headache, abdominal pain, and fibromyalgia. Effective strategies include cognitive-behavioral skills training, parent training, relaxation therapy, and biofeedback. The relative or comparative effectiveness of different interventions has been examined in studies of headache and abdominal pain in children. Biofeedback and relaxation therapies have been found to have superior effects to pharmacologic treatments in reducing headache pain in children and adolescents. Similarly, for recurrent abdominal pain, positive effects for CBT were found relative to pharmaceutical, botanical, and dietary interventions (which had very weak evidence).

Nonpharmacologic treatments of pain may be generalized to other treatment needs. A child with cancer who learns self-hypnosis to reduce distress from lumbar punctures may successfully apply this skill to other stressful medical and nonmedical situations. When deciding how to incorporate nonpharmacologic techniques to treat pain, the practitioner should: (1) pay attention to the patient's environment, optimal positioning, and physical comfort; (2) seek to integrate nonpharmacologic techniques with appropriate analgesics; (3) give children (and family members) developmentally and situationally appropriate information as to what to expect, given the child's medical condition, procedures, and treatments; (4) include patients and their families in decision making to ensure an appropriate treatment choice and to optimize adherence to treatment protocols; and (5) above all, develop a **communication plan** among the different therapists, typically with the pediatrician as the case manager, so that the messages to the child and parent are consistent and the modes of therapy are organized into an **integrative team approach**.

Cognitive-behavioral strategies refer to techniques that teach children how to manage pain by learning new ways to think about the pain and to change behaviors associated with the pain. This includes strategies aimed at enhancing children's confidence and self-efficacy, decreasing fear of pain, and promoting exposure to previously avoided activities. In addition, pain coping skills may shift the child's attentional focus away from pain and painful stimuli. Behavioral strategies focused on modifying contingencies in the child's environment (such as parental responses to pain behaviors) may influence pain expression, leading to changes in how children behave or respond to pain. Strategies may also be aimed specifically at modifying individual and family coping (e.g., difficulties in social relationships, psychosocial distress).

Parent and family education and/or psychotherapy, particularly cognitive-behavioral family approaches, have been shown to be effective for treating chronic pain. Parents can learn to cope with their own distress and to understand pain mechanisms and appropriate treatment of pain. Key strategies include teaching parents to alter family patterns that may inadvertently exacerbate pain through developing behavior plans. Parents are taught to create plans for the child to manage the child's own symptoms and increase independent functioning. Often, all adult caregivers (e.g., parents and teachers) need

guidance on developing a behavioral incentive plan to help the child return to school, gradually increase attendance, and receive tutoring, after a prolonged, pain-related absence.

Other Psychologic or Psychiatric Treatment

In addition to pain, there may be other psychologic disorders (e.g., anxiety disorders, major depression) that should be identified and addressed either as part of or separate from the pain management plan. Individual psychotherapy or psychiatric intervention may be warranted to adequately treat a comorbid disorder.

Relaxation techniques promote muscle relaxation and reduction of anxiety, which often accompanies and increases pain. Controlled breathing and progressive muscle relaxation are commonly used relaxation techniques for preschool-age and older children. Asking the child to focus on the breath and pretend to be blowing up a big balloon, while pursing the lips and exhaling slowly may help induce controlled breathing.

Distraction helps a child of any age shift attention away from pain and onto other activities. Common attention sustainers in the environment include bubbles, music, video games, television, the telephone, conversation, school, and play. Asking children to tell stories, or asking parents to read to the child, and even mutual story-telling can be helpful distracters. Being involved with social, school, physical, or other activities helps the child in chronic pain to regain function.

Hypnotherapy helps a child focus on an imaginative experience that is comforting, safe, fun, or intriguing. Hypnotherapy captures the child's attention, alters his sensory experiences, reduces distress, reframes pain experiences, creates time distortions, helps the child dissociate from the pain, and enhances feelings of mastery and self-control. Children with chronic pain can use metaphor, for example, imagining they have overcome something feared because of pain in real life. As the child increases mastery of imagined experiences, the enhanced sense of control can be used during actual pain rehabilitation. Hypnotherapy is best for children of school age or older.

Biofeedback involves controlled breathing, relaxation, or hypnotic techniques with a mechanical device that provides visual or auditory feedback to the child when the desired action is approximated. Common targets of actions include muscle tension, peripheral skin temperature through peripheral vasodilation, and anal control through rectal muscle contraction and relaxation. Biofeedback also enhances the child's sense of mastery and control, especially for the child who needs more "proof" of change than that generated through hypnotherapy alone.

Iyengar yoga was developed to achieve balance in mind, body, and spirit. This form of therapeutic yoga is especially effective for treating chronic pain; improving mood, energy, and sleep; and reducing anxiety. Iyengar yoga involves a series of asanas (body poses) oriented to the specific medical condition or symptoms. It uses props, such as blankets, bolsters, blocks, and belts, to support the body while the patient assumes more healing poses. Yoga promotes a sense of energy, relaxation, strength, balance, and flexibility and, over time, enhances a sense of mastery and control. In more advanced yoga, the child may learn certain types of breathing (pranayama) for added benefit. Mostly, through this form of yoga, the child learns mindfulness or being present and in the moment. By focusing on body and breath, the child can develop strategies to avoid ruminating about the past or worrying about the future.

Massage therapy involves the therapist's touching and applying varied degrees of pressure on the child's muscles. This massage is very useful for children with chronic pain and especially helpful for those with myofascial pain. There are several types of massage, including craniosacral therapy. For young children, it can be helpful to have parents learn and perform brief massage on their children before bedtime.

Physical therapy can be especially useful for children with chronic, musculoskeletal pain and for those deconditioned from inactivity. Exercise appears to specifically benefit muscle functioning, circulation, and posture, also improving body image, body mechanics, sleep, and mood. The physical therapist and the child can develop a graded exercise plan for enhancing the child's overall function.

Acupuncture involves the placement of needles at specific acupuncture points along a meridian, or energy field, after a diagnosis of excess or deficienct energy in that meridian as the primary cause of the pain is made by the acupuncturist. Acupuncture is a feasible, popular part of a pain management plan for children with chronic pain. Acupuncture alleviates chronic nausea, fatigue, and several chronic pain states, including migraine and chronic daily headaches, abdominal pain, and myofascial pain. Acupuncture also has efficacy in adults with myofascial pain, primary dysmenorrhea, sickle cell crisis pain, and sore throat pain. The acupuncturist must relate well to children so that the experience is not traumatic, because added stress would undo the benefits gained.

Transcutaneous electrical nerve stimulation (TENS) is the use of a battery-operated tool worn on the body to send electrical impulses into the body at certain frequencies set by the machine. TENS is believed to be quite safe and can be tried for many forms of localized pain. Children often find TENS helpful and effective.

Music and art therapy can be especially helpful for young and nonverbal children who would otherwise have trouble with traditional talk psychotherapies. Also, many creative children can more easily express fears and negative emotions through creative expression and, with the therapist's help, learn about themselves in the process.

Dance, movement, pet therapies, and aromatherapy have also been used and may be very helpful but have not been well studied in children for pain control.

Invasive Interventions in Treating Pain

Interventional neuraxial and peripheral nerve blocks provide intraoperative anesthesia, postoperative analgesia (see Chapter 61), treatment of acute pain (e.g., long bone fracture and the pain of acute pancreatitis), and contribute to the management of chronic pain (e.g., headaches, abdominal pain, complex regional pain syndromes [CRPS], and cancer pain). Even though interventional procedures are typically rarely used in nonmalignant chronic pain in children, they are described here so that the pediatrician will understand the different types of procedures that are more commonly carried out in adults and rarely described in pediatric texts.

Regional anesthesia provides several benefits: (1) it is an alternative to or augmentation of opioid-based pain control, thereby minimizing the opioid side effects of nausea, vomiting, somnolence, respiratory depression, pruritus, constipation, and physical dependence; (2) it generally provides better quality pain relief because it interrupts nociceptive pathways and more profoundly inhibits endocrine stress responses; (3) it results in earlier ambulation in recovering surgical patients; (4) it helps prevent atelectasis in the setting of severe chest pain; and (5) it usually results in earlier discharge from the hospital. Theoretically, the interruption of nociceptive pathways in the periphery by regional anesthetics will prevent, or reverse the process of amplification of pain signals induced by nociception (CNS wind-up, glial cell activation, etc.). For postoperative pain, effective regional anesthesia and good analgesia reduce the risks of acute pain transitioning into chronic pain.

Regional anesthesia is considered safe and effective if performed by trained staff with the proper equipment. Most nerve blocks are performed by an anesthesiologist or pain management physician; a few are easily performed by a nonanesthesiologist with appropriate training.

Head and Neck Blocks

Primary pain syndromes of the head, such as trigeminal neuralgia, are distinctly unusual in the pediatric population, and few surgical procedures in the head and neck are amenable to regional anesthesia. Pain following tonsillectomies is not amenable to nerve blockade, and neurosurgical incisional pain is usually mitigated by local infiltration of local anesthetic into the wound margins by the surgeon. Headache disorders, very common in the pediatric age group, often respond well to block of the greater and lesser occipital nerves, which provide sensation to much of the cranial structures, from the anterior hairline to the cervical region. The greater occipital nerve can be blocked adjacent to the occipital artery, which can usually be identified at the occipital

ridge midway between the occipital prominence and the mastoid process by palpation, Doppler sound amplification, or visually by ultrasound. The lesser occipital nerves emerge from deeper layers midway between the greater occipital nerve and the mastoid process, where subcutaneous infiltration is effective.

Upper-Extremity Blocks

The brachial plexus block controls pain during surgical procedures or other lesions of the upper extremities. This block also protects the extremity from movement, reduces arterial spasm, and blocks sympathetic outflow to the upper extremity. The brachial plexus, responsible for cutaneous and motor innervation of the upper extremity, is an arrangement of nerve fibers originating from spinal nerves C5 through C8 and T1, extending from the neck into the axilla, arm, and hand. The brachial plexus innervates the entire upper limb, except for the trapezius muscle and an area of skin near the axilla. If pain is located proximal to the elbow, the brachial plexus may be blocked above the clavicle (roots and trunks); if the pain is located distal to the elbow, the brachial plexus may be blocked below it (cords and nerves). The block may be given as a single injection with a long-acting anesthetic (bupivacaine or ropivacaine, sometimes augmented with clonidine or dexamethasone to prolong block duration and intensity) to provide up to 12 hr of analgesia, or given via a catheter (to infuse local anesthetic) attached to a pump that can provide continuous analgesia over days or even weeks.

Anesthesiologists frequently use an IV regional block (or Bier block) with a local anesthetic in combination with a vasodilator such as phentolamine and an NSAID (typically ketorolac) to manage the pain of CRPS. The technique requires placement of an IV cannula into the distal part of the affected extremity, exsanguination of the extremity by elevating and wrapping it in an elastic (Esmarch) bandage, and application of a double pneumatic tourniquet, which is then inflated. Local anesthetic with additives as indicated is then injected into the IV cannula, filling the exsanguinated vasculature. The tourniquet must remain inflated for at least 30 min to allow fixation of local anesthetic to tissues, which reduces peak blood concentration and toxicity upon tourniquet deflation. Although the anesthetic effect is limited to the time of tourniquet inflation, analgesia for pain disorders usually persists for days, weeks, or months after the block.

Trunk and Abdominal Visceral Blocks

Trunk blocks provide somatic and visceral analgesia and anesthesia for pain or surgery of the thorax and abdominal area. Sympathetic, motor, and sensory blockade may be obtained. These blocks are often used in combination to provide optimal relief. Intercostal and paravertebral blocks may be beneficial in those patients for whom an epidural injection or catheter is contraindicated, for example, in the patient with a coagulopathy. Respiratory function is maintained, and the side effects of opioid therapy are eliminated.

The intercostal, paravertebral, rectus sheath, and transverse abdominal plane blocks are the most useful ones for pediatric chest and abdominal pain. The celiac plexus block is most useful for visceral pain caused by malignant cancer or pancreatitis. A pediatrician may perform an intercostal block, but the other blocks are best performed by an experienced anesthesiologist or pain physician.

The intercostal block is used to block the intercostal nerves, the anterior rami of the thoracic nerves from T1 to T11. These nerves lie inferior and posterior to each rib, and between the inner and innermost intercostal muscles, with their corresponding vein and artery, where they can be blocked, generally posterior to the posterior axillary line. Ultrasound imaging of the intercostal nerves helps avoid injury to intercostal vessels or insertion of the needle through the pleura, which results in pneumothorax.

The paravertebral block, an alternative to intercostal nerve block or epidural analgesia, is useful for pain associated with thoracotomy or with unilateral abdominal surgery, such as nephrectomy or splenectomy. Essentially this block results in multiple intercostal blocks with a single injection. The thoracic paravertebral space, lateral to the vertebral column, contains the sympathetic chain, rami communicantes, and dorsal and ventral roots of the spinal nerves. Because it is a continuous space, local anesthetic injection will provide sensory, motor, and sympathetic blockade to several dermatomes. The paravertebral block may be performed as a single injection, or, for a very prolonged effect, as a continuous infusion over several days or weeks via a catheter inserted in the paravertebral space. This block is best performed by an anesthesiologist or interventional pain physician.

Ilioinguinal and iliohypogastric nerve blocks are indicated for surgery for inguinal hernia repair, hydrocele, or orchiopexy repair as well as for chronic pain subsequent to these procedures. The first lumbar nerve divides into the iliohypogastric and ilioinguinal nerves, which emerge from the lateral border of the psoas major muscle. The iliohypogastric nerve supplies the suprapubic area as it pierces the transversus abdominis muscle and runs deep to the internal oblique muscle. The ilioinguinal nerve supplies the upper medial thigh and superior inguinal region as it also pierces the transversus abdominis muscle and runs across the inguinal canal. Ultrasound guidance has made this nerve block nearly always successful.

The **celiac plexus block** is indicated for surgery or pain of the pancreas and upper abdominal viscera. The celiac plexus, located on each side of the L1 vertebral body, contains 1-5 ganglia. The aorta lies posterior, the pancreas anterior, and the inferior vena cava lateral to these nerves. The celiac plexus receives sympathetic fibers from the greater, lesser, and least splanchnic nerves, as well as from parasympathetic fibers from the vagus nerve. Autonomic fibers from the liver, gallbladder, pancreas, stomach, spleen, kidneys, intestines, and adrenal glands originate from the celiac plexus. This block requires CT guidance or fluoroscopy to provide direct visualization of the appropriate landmarks and to confirm correct needle placement. The close proximity of structures such as the aorta and vena cava make this a technical procedure best performed by an anesthesiologist, interventional pain physician, or radiologist.

Lower-Extremity Blocks

Lumbar plexus and sciatic nerve blocks provide pain control for painful conditions or surgical procedures of the lower extremities, with the benefit of providing analgesia to only 1 extremity while preserving motor and sensory function of the other. Unlike with some caudal or lumbar epidural blocks, the patient may still bear weight on the affected leg. The lumbosacral plexus is an arrangement of nerve fibers originating from spinal nerves L2-L4, and S1-S3. The lumbar plexus arises from L2-L4 and divides into the lateral femoral cutaneous, femoral, and obturator nerves. These nerves supply the muscles and sensation of the upper leg, with a sensory branch of the femoral nerve extending below the knee to innervate the medial aspect of the foreleg, ankle, and foot (saphenous nerve). The sacral plexus arises from L4-S3 and divides into the major branches of the sciatic, tibial, and common peroneal nerves. These nerves, in turn, supply the posterior thigh, lower leg, and foot. Unlike brachial plexus blocks, whose targets are accessible, blockade of the entire lower extremity requires more than 1 injection because the lumbosacral sheath is not accessible. Separate injections are necessary for the posterior (sciatic) and anterior (lumbar plexus) branches; the injections can be performed at any of several levels during the course of the nerve, as is clinically expedient. The lumbar plexus can be blocked in the back, resulting in analgesia of the femoral, lateral femoral cutaneous, and obturator nerves. Alternatively, any of these 3 nerves can be individually anesthetized, depending on the location of the pain. Similarly, the sciatic nerve can be anesthetized proximally as it emerges from the pelvis or more distally in the posterior thigh, or its major branches (the tibial and peroneal nerves) can be individually anesthetized. These nerve blocks are generally best performed by an anesthesiologist, interventional pain physician, or radiologist.

Sympathetic Blocks

Sympathetic blocks were once thought to be useful in the diagnosis and treatment of sympathetically mediated pain, CRPS, and other neuropathic pain conditions, but more recently large meta-analyses have shown their utility to be small. The peripheral sympathetic trunk is formed by the branches of the thoracic and lumbar spinal segments,

and it extends from the base of the skull to the coccyx. The sympathetic chain, which consists of separate ganglia containing nerves and autonomic fibers with separate plexuses, can be differentially blocked. These separate plexuses include the stellate ganglion in the lower neck and upper thorax, the celiac plexus in the abdomen, the second lumbar plexus for the lower extremities, and the ganglion impar for the pelvis. When blocks of these plexuses are performed, sympathectomy is obtained without attendant motor or sensory anesthesia.

The **stellate ganglion block** is indicated for pain in the face or upper extremity as well as for CRPS, phantom limb pain, amputation stump pain, or circulatory insufficiency of the upper extremities. The stellate ganglion arises from spinal nerves C7-T1 and lies anterior to the 1st rib. It contains ganglionic fibers to the head and upper extremities. Structures in close proximity include the subclavian and vertebral arteries anteriorly, the recurrent laryngeal nerve, and the phrenic nerve. The Chassaignac tubercle, the transverse process of the C6 vertebral body superior to the stellate ganglion, is a useful and easily palpable landmark for the block, but radiographic or ultrasound imaging is more typically used than surface anatomy and palpation.

The lumbar sympathetic block addresses pain in the lower extremity, CRPS, phantom limb pain, amputation stump pain, and pain from circulatory insufficiency. The lumbar sympathetic chain contains ganglionic fibers to the pelvis and lower extremities. It lies along the anterolateral surface of the lumbar vertebral bodies and is most often injected between the L2 and L4 vertebral bodies.

The analgesia produced by peripheral sympathetic blocks usually outlives the duration of the local anesthetic, often persisting for weeks or indefinitely. If analgesia is transient, the blocks may be performed with catheter insertion for continuous local anesthesia of the sympathetic chain over a period of days or weeks. Because precise radiographically guided placement of the needle and/or catheter is required for safety and success, sympathetic blocks are generally best performed by an anesthesiologist, interventional pain physician, or interventional radiologist.

Epidural Anesthesia (Thoracic, Lumbar, and Caudal)

Epidural anesthesia and analgesia are indicated for pain below the clavicles, management of CRPS, cancer pain unresponsive to systemic opioids, and pain limited by opioid side effects.

The 3 layers of the spinal meninges—the dura mater (outer), the arachnoid mater (middle), and the pia mater (inner)—envelop the spinal neural tissue. The subarachnoid space contains cerebrospinal fluid between the arachnoid mater and pia mater. The epidural space extends from the foramen magnum to the sacral hiatus. The epidural space, which contains fat, lymphatics, blood vessels, and the spinal nerves as they leave the spinal cord, separates the dura mater from the periosteum of the surrounding vertebral bodies. In children, the fat in the epidural space is not as dense as in adults, predisposing to greater spread of the local anesthetic from the site of injection.

Epidural local anesthetics block both sensory and sympathetic fibers, and if the local anesthetic is of sufficient concentration, they also block motor fibers. Mild hypotension may occur, although it is unusual in children younger than 8 yr. Epidural local anesthetics high in the thoracic spine may also anesthetize the sympathetic nerves to the heart (the cardiac accelerator fibers), producing bradycardia. In addition to using local anesthetics, it is routine to use opioids and α-agonists in the epidural space. These agents have their primary site of action in the spinal cord, to which they diffuse from their epidural depot. Side effects of epidural opioid administration include delayed respiratory depression, particularly when hydrophilic opioids such as morphine are used. The risk of this effect requires that children receiving epidural opioids by intermittent injection or continuous infusion be monitored by continuous pulse oximetry and nursing observation, particularly during the 1st 24 hr of therapy or after significant dose escalations. Respiratory depression occurring after the 1st 24 hr of epidural opioid administration is distinctly unusual.

Epidural clonidine, an α_2-agonist with μ-opioid analgesic properties, is associated with minimal risk and side effects. Although product labeling indicates use only in children with severe cancer pain, it is commonly used for routine postoperative pain as well as pain syndromes such as CRPS. Mild sedation is the most common side effect of epidural clonidine, and it is not associated with respiratory depression.

Because performing epidural blockade is technical and may result in spinal cord injury, it is best done by an anesthesiologist or pain physician skilled in the technique.

INTRATHECAL ANALGESIA

Intrathecal catheters infused with opioids, clonidine, ziconotide, and local anesthetics are occasionally applicable in pediatric patients suffering from intractable pain from cancer or other conditions. Typically, intrathecal catheters are attached to an implanted electronic pump containing a drug reservoir sufficient for several months of dosing. The technique is technical and best performed by an experienced pain management physician.

NERVE ABLATION AND DESTRUCTION

In infrequent pediatric cases, pain remains refractory in spite of maximal reliance upon oral and IV medications and nerve blockade. In these instances, temporary (ablation) or permanent (lytic) destruction of 1 or more nerves may be performed. These situations are rather extraordinary in children, and the techniques should be carefully weighed against the consideration of inducing permanent nerve destruction in a growing child with decades of life ahead. On the other hand, when pain is severe in life-limiting disease processes, the long-term considerations are less concerning, and these techniques should be discussed with a pain management specialist skilled in their performance.

CONSIDERATIONS FOR SPECIAL PEDIATRIC POPULATIONS

Pain Perception and Effects of Pain on Newborns and Infants

There are a number of sources of pain in the newborn period. These include acute pain (diagnostic and therapeutic procedures, minor surgery, monitoring), continuous pain (pain from thermal/chemical burns, postsurgical and inflammatory pain), and chronic or disease-related pain (repeated heelsticks, indwelling catheters, necrotizing enterocolitis, nerve injury, chronic conditions, thrombophlebitis). The most common sources of pain in healthy infants are acute procedures, such as heel lances, operations, and, in boys, circumcision.

In premature infants in the neonatal intensive care unit (NICU), there are many procedures performed. In the 1st wk of life, approximately 94% of preterm infants younger than 28 wk of gestational age are ventilated. Other procedures are heelsticks (the most commonly performed) and airway suctioning. Only a few of these procedures are preceded by any type of analgesia. Repeated handling and acute pain episodes sensitize the neonate to increased reactivity and stress responses to subsequent procedures they undergo as neonates or children. Typical stress responses include increases in heart rate, respiratory rate, blood pressure, and intracranial pressure. Cardiac vagal tone, transcutaneous oxygen saturation, carbon dioxide levels, and peripheral blood flow are decreased. Autonomic signs include changes in skin color, vomiting, gagging, hiccupping, diaphoresis, dilated pupils, and palmar and forehead sweating.

To assess pain in the newborn, it is critical to observe the infant for facial expression, body movements, crying, and any other atypical functional behaviors. The observer must consider the context in which the behavior is experienced. The infant's state (agitated, alert, asleep) and gestational and post-gestational ages also affect behavioral stress responses.

Untreated pain in the newborn has serious short-term and longer-term consequences. There has been a shift in most NICUs to more liberal use of opioids. Nonetheless, morphine, the traditional gold standard of analgesia for acute pain, may not be very effective and may have adverse long-term consequences. No differences have been found in the incidence of severe intraventricular hemorrhage or in the mortality rate when infants receiving morphine are compared with the

placebo group, and there are no changes in assessed pain from tracheal suctioning in ventilated infants receiving morphine compared with those receiving a placebo infusion. Morphine may not alleviate acute pain in ventilated preterm neonates, although there are few data on the effects of morphine and fentanyl in nonventilated newborns. The lack of opioid effects for acute pain in neonates may be due to an immaturity of opioid receptors; acute pain may cause the uncoupling of μ opioid receptors in the forebrain. Repetitive acute pain may create central neural changes in the newborn that may have long-term consequences for later pain vulnerability, cognitive effects, and opioid tolerance. There are both anatomic and behavioral manifestations of the adverse effects of neonatal stress, including pain, on brain development. Most neonatologists use opioids in painful situations. Sucrose and pacifiers are also being used in the NICU. The effects of sucrose (sweet taste) are believed to be opioid-mediated because they are reversed with naloxone; stress and pain relief are integrated through the endogenous opioid system. Sucrose, with or without a pacifier, may be effective for acute pain and stress control. Other nonpharmacologic strategies for stress and pain control include infant care by an individual primary nurse, tactile-kinesthetic stimuli (massage), "kangaroo care," and soothing sensorial saturation.

Children with Cancer Pain

The World Health Organization proposed an analgesic therapy model for cancer pain known as the *analgesic ladder* (Table 62-11). Designed to guide therapy in the Third World, this ladder consists of a hierarchy of oral pharmacologic interventions intended to treat pain of increasing magnitude. The hierarchy ignores modalities such as the use of nonconventional analgesics and interventional pain procedures, which are within the capability of physicians to prescribe in developed countries. Nevertheless, because oral medications are simple and efficacious, especially for home use, the ladder presents a framework for rationally using them before applying other drugs and techniques of drug administration.

Oral medications are the 1st line of analgesic treatment. Because NSAIDs affect platelet adhesiveness, they are typically not used. Opioid therapy is the preferred approach for moderate or severe pain. Nonopioid analgesics are used for mild pain, a weak opioid is added for moderate pain, and strong opioids are administered for more severe pain. Adjuvant analgesics can be added, and side effects and comorbid symptoms are actively managed. Determining the type and sources of the pain will help develop an effective analgesic plan. Certain treatments, such as the chemotherapeutic agent vincristine, are associated with neuropathic pain. Such pain might require anticonvulsants or TCAs. Organ-stretching pain from tumor growth within an organ might require strong opioids and/or radiation therapy if the tumor is radiosensitive. Organ obstruction, such as intestinal obstruction, should be diagnosed to relieve or bypass the obstruction.

It is important to consider both pharmacologic and nonpharmacologic strategies (e.g., cognitive-behavioral treatment, family and parent support) to treat pain in children with cancer.

Table 62-11	World Health Organization Analgesic Ladder for Cancer Pain
STEP 1 Patients who present with mild to moderate pain should be treated with a nonopioid.	
STEP 2 Patients who present with moderate to severe pain or for whom the step 1 regimen fails should be treated with an oral opioid for moderate pain combined with a nonopioid analgesic.	
STEP 3 Patients who present with very severe pain or for whom the step 2 regimen fails should be treated with an opioid used for severe pain, with or without a nonopioid analgesic.	

Children with Pain Associated with Advanced Disease

Patients with advanced diseases, including cancer, AIDS, neurodegenerative disorders, and cystic fibrosis, need palliative care approaches that focus on optimal quality of life. Nonpharmacologic and pharmacologic means of management of pain and other distressing symptoms are palliative care's key components. It should be highlighted here that "palliative care" should be offered to all children with serious diseases, whether or not the diseases are potentially curable and whether or not long life expectancy is predicted. Examples include young children diagnosed with acute lymphoblastic leukemia (>90% posttreatment life expectancy) and children undergoing organ transplantation. Palliative care in pediatrics is meant to connote treatment that focuses on symptom reduction, quality of life, and good family and clinical team communication. It is not just reserved for patients in hospice care or those at the end of life. Differences among these conditions that relate to the progression of underlying illness, associated distressing symptoms, and common emotional responses should shape individual treatment plans (see Chapter 43). For end-of-life care, more than 90% of children and adolescents with cancer can be made comfortable by standard escalation of opioids according to the World Health Organization protocol. A small subgroup (5%) has enormous opioid dose escalation to >100 times the standard morphine or other opiate infusion rate. In most of these cases, there is spread of solid tumors to the spinal cord, roots, or plexus, and signs of neuropathic pain are evident. Methadone given orally is often used in palliative care, not just end of life care, because of its long half-life and its targeting of both opioid and *N*-methyl-D-aspartate receptors. The type of pain experienced by the patient (neuropathic, myofascial) should determine the need for adjunctive agents. Complementary measures, such as massage, hypnotherapy, and/or spiritual care, should also be considered in palliative care. Although the oral route of opioid administration should be encouraged, especially to facilitate care at home if possible, some children are unable to take oral opioids. Transdermal and sublingual routes, as well an intravenous infusion with a PCA, are likely next choices. Small, portable infusion pumps are convenient for home use. If venous access is limited, a useful alternative is to administer opioids (especially morphine or hydromorphone, but not methadone or meperidine) through continuous subcutaneous infusion, with or without a bolus option. A small (e.g., 22-gauge) cannula is placed under the skin and secured on the thorax, abdomen, or thigh. Sites may be changed every 3-7 days, as needed. As noted, alternative routes for opioids include the transdermal and oral transmucosal routes. These latter routes are preferred over IV and subcutaneous drug delivery when the patient is being treated at home.

Examples of Chronic and Recurrent Pain Syndromes

Chronic pain is defined as recurrent or persistent pain lasting longer than the normal tissue healing time, approximately 3-6 mo. Children may experience pain related to injury (e.g., burns) or a chronic or underlying disease process (e.g., cancer, arthritis); pain can also be the chronic condition itself (e.g., CRPS, fibromyalgia, functional abdominal pain). During childhood, abdominal, musculoskeletal, and headache pain are the most frequently occurring conditions. However, definitions of chronic pain do not take into account standard criteria for assessing particular pain symptoms or for evaluating the intensity or impact of pain, and therefore include individuals with varying symptoms and experiences. Consequently, in epidemiologic surveys, prevalence estimates vary widely. Overall prevalence rates for different childhood pains range from 4-88%. For example, an average of 13.5-31.8% of adolescents in a community sample reported having weekly abdominal, headache, or musculoskeletal pains. Most epidemiologic studies report prevalence and do not report the severity or impact of the pain. Research indicates that only a subset of children and adolescents with chronic pain (approximately 5%) experience moderate-severe disability, and this likely better represents the estimated population for whom help is needed to treat pain and associated problems.

COMPLEX REGIONAL PAIN SYNDROMES

Neuropathic pain is caused by abnormal excitability in the peripheral or CNS that may persist after an injury heals or inflammation subsides. The pain, which can be acute or chronic, is described as burning or stabbing and may be associated with cutaneous hypersensitivity (allodynia), distortion of sensation (dysesthesia), and amplification of noxious sensations (hyperalgesia and hyperpathia). Neuropathic pain conditions may be responsible for >35% of referrals to chronic pain clinics, conditions that commonly include posttraumatic and postsurgical peripheral nerve injuries, phantom pain after amputation, pain after spinal cord injury, and pain caused by metabolic neuropathies. Neuropathic pain typically responds poorly to opioids. In adults, evidence suggests the efficacy of TCAs (nortriptyline, amitriptyline) and anticonvulsants (gabapentin, pregabalin) for treatment of neuropathic pain (see Tables 62-9 and 62-10).

CRPS type 1, formerly known as reflex sympathetic dystrophy, is well-described in the pediatric population. CRPS type 1 is a syndrome of neuropathic pain that typically follows an antecedent and usually minor injury to an extremity without identifiable nerve injury. The syndrome of CRPS type 1 includes severe spontaneous neuropathic pain, hyperpathia, hyperalgesia, severe cutaneous allodynia to touch and cold, changes in blood flow (typically extremity cyanosis), and sweating. In more advanced cases, symptoms include dystrophic changes of the hair, nails, and skin, immobility of the extremity (dystonia), and muscle atrophy. In the most advanced cases, symptoms include ankylosis of the joints of the extremity. Specific causal factors in CRPS type 1 in both children and adults remain elusive, although coincidental events may be noted. **CRPS type 2**, formerly referred to as causalgia, is less common.

The syndromes of CRPS type 2 and CRPS type 1 are virtually identical, except that the former is associated with a well-defined peripheral nerve injury. Treatment of CRPS in children has been extrapolated from that in adults, with some low-level evidence for efficacy of physical therapy, cognitive-behavioral therapy, nerve blocks, TCAs, gabapentin, and some other related drugs. All experts in pediatric pain management agree on the value of aggressive physical therapy. Some centers provide aggressive therapy without the use of pharmacologic agents or interventional nerve blocks; unfortunately, recurrent episodes may be seen in up to 50% of patients. Physical therapy can be extraordinarily painful for children to endure; it is tolerated only by the most stoic and motivated patients. If children have difficulty enduring the pain, there is a well-established role for using pharmacologic agents with or without peripheral or central neuraxial nerve blocks to render the affected limb sufficiently analgesic so that physical therapy can be tolerated. Pharmacologic interventions include the use of AEDs such as gabapentin and/or TCAs such as amitriptyline (see Fig. 62-4). Although there is clear evidence of a peripheral inflammatory component of CRPS, with release of cytokines and other inflammatory mediators from the peripheral nervous system in the affected limb, the use of antiinflammatory agents has been disappointing. Commonly used nerve block techniques include sympathetic nerve blocks, IV regional anesthetics, epidural analgesia, and peripheral nerve blocks. In extreme and refractory cases, more invasive strategies have been reported, including surgical sympathectomy and spinal cord stimulation. Although an array of treatments have some benefit, the mainstay of treatment remains physical therapy emphasizing desensitization, strengthening, and functional improvement. Additionally, pharmacologic agents and psychologic and complementary therapies are important components of a treatment plan. Invasive techniques, although not curative, are valuable if they permit the performance of frequent and aggressive physical therapy that cannot be carried out otherwise. Some children with CRPS become so easily sensitized that persistent and bothersome pain may develop at the site of the invasive procedure. A good biopsychosocial evaluation will help determine the orientation of the treatment components. At this time, there are insufficient data to indicate the superior value of interventional blocks, such as epidural anesthesia delivery, in children with CRPS type I, over physical and psychologic interventions, with or without pharmacological support.

MYOFASCIAL PAIN DISORDERS AND FIBROMYALGIA

Myofascial pain disorders are associated with tender points in the affected muscles as well as with muscle spasms (tight muscles). Treatment is targeted at relaxing the affected muscles through physical therapy, Iyengar yoga, massage, and/or acupuncture. Rarely are pharmacologic muscle relaxants helpful other than for creating tiredness at night for sleep. Dry needling or injections of local anesthetic into the tender points has been advocated, but the data do not support this as a standard treatment. Similarly, although botulinum toxin injections may be used, no data support this practice in children. Often poor body postures, repetitive use of a part of the body not used to that movement, or carrying heavy backpacks initiates pain. When it becomes widespread with multiple tender points, the diagnosis may be made of juvenile fibromyalgia, which may or may not continue to subsequently become adult fibromyalgia. Likely there are different subtypes of widespread pain syndromes, and physical therapy is a key component of treatment. Psychologic interventions may play an important role to assist the child in resuming normal activities and to manage any psychologic comorbidities. Any pain rehabilitation plan should enhance return to full function. Because there is a high incidence of chronic pain in parents of children presenting with a chronic pain condition, especially fibromyalgia, attention to parent and family factors is important. Parent training may entail teaching the parent to model more appropriate pain coping behaviors and to recognize the child's independent attempts to manage pain and function adaptively. Parents may also need referrals to obtain appropriate pain management for their own pain condition.

The drugs pregabalin and duloxetine have both been approved for management of fibromyalgia in adults in the United States, but there are no clinical studies confirming their effectiveness in children and adolescents.

ERYTHROMELALGIA

Erythromelalgia in children is generally primary, whereas in adults it may be either primary or secondary to malignancy or other hematologic disorders such as polycythemia vera. Patients with this disorder exhibit red, warm, hyperperfused distal limbs. The disorder is usually bilateral, and it may involve either or both the hands and feet. Patients perceive burning pain and typically seek relief by immersing the affected extremities in ice water, sometimes so often and for so long so that skin pathology results. Primary erythromelalgia has recently been shown to be caused by a genetic mutation in the gene for the NaV1.7 neuronal sodium channel on peripheral C nociceptive fibers, resulting in their spontaneous depolarization, and thus continuous burning pain. The most common mutation identified is in the *SCN9A* gene, although there are several mutations that affect the NaV1.7 channel. Interestingly, another mutation in the NaV1.7 channel results in a rare but devastating genetic condition, the congenital indifference to pain.

It is easy to distinguish erythromelalgia (or related syndromes) from CRPS. The limb afflicted with CRPS is typically cold and cyanotic, the disease is typically unilateral, and children with CRPS have cold allodynia, making immersion in cold water exquisitely painful; in erythromelalgia, ice water immersion is analgesic, the condition is bilateral and symmetrical, and associated with hyperperfusion of the distal extremity. The evaluation of hyperperfused limbs with burning pain should include genetic testing for Fabry disease and screening for hematologic malignancies, with diagnosis of primary erythromelalgia being one of exclusion. There are presently few clinical laboratories that are certified to perform the DNA analysis required to identify the common NaV1.7 mutations.

The definitive treatment of Fabry disease includes enzyme replacement as disease-modifying treatment and administration of neuropathic pain medications, such as gabapentin, although the success of antineuropathic pain drugs in small-fiber neuropathies has not been impressive. The treatment of erythromelalgia is far more problematic. Antineuropathic pain medications, such as AEDs and TCAs are typically prescribed but rarely helpful (see Fig. 62-4). Although one might predict that sodium channel–blocking AEDs might be effective in this

sodium channelopathy, oxcarbazepine has not proven to be a particularly effective modality. The pain responds well to regional anesthetic nerve blocks, but it returns immediately when the effects of the nerve block resolve. In contrast, in other neuropathic syndromes, the analgesia usually (and inexplicably) persists well after the resolution of the pharmacologic nerve block. Aspirin and even nitroprusside infusions are reported to be of benefit with secondary erythromelalgia, but they are not reported to be helpful in children with primary erythromelalgia. There are case reports in adults and clinical experience in children suggesting that periodic treatment with high-dose capsaicin cream is effective in alleviating the burning pain and disability of erythromelalgia. Capsaicin (essence of chili pepper) cream is a vanilloid receptor (TRPV1) agonist that depletes small-fiber peripheral nerve endings of the neurotransmitter substance P, which is an important neurotransmitter in the generation and transmission of nociceptive impulses. Once depleted, these nerve endings are no longer capable of generating spontaneous pain until the receptors regenerate, a process that takes many months.

OTHER CHRONIC PAIN CONDITIONS IN CHILDREN

It should be noted that there are a variety of genetic and other medical/surgical conditions that are often associated with chronic pain. Examples include Fabry disease, Chiari/syringomyelia, juvenile idiopathic arthritis, mitochondrial disorders, degenerative neurologic diseases, cerebral palsy, autism spectrum disorders, intestinal pseudoobstruction, inflammatory bowel disease, chronic migraine and chronic daily headaches, irritable bowel disease, and others. In many cases, treating the underlying disease, such as enzyme replacement in Fabry disease and in other lysosomal disorders, will reduce what otherwise might be progression of symptoms, but may not totally reduce pain and suffering, and other modalities will be needed. Finally, pain that persists and is not well treated can lead to central sensitization and widespread pain, such as seen in children with one pain source who develop fibromyalgia.

MANAGING COMPLEX CHRONIC PAIN PROBLEMS

Some patients with chronic pain have a prolonged course of evaluation in attempts to find what is expected as the singular "cause" of the pain, and thus also undergo many failed treatments. Parents worry that the doctors have not yet discovered the cause that may be serious and life-threatening, and children often feel not believed, that they are faking their pain, or are "crazy." There may be no identifiable or diagnosable condition and families may seek opinions from multiple treatment facilities in an attempt to find help for their suffering child. In fact, in many cases what may have begun as an acute injury or infectious event may result for some children into a chronic pain syndrome, with changes in the neurobiology of the pain signaling system.

In the context of disabling chronic pain, it is very important for the pediatrician to (1) avoid overmedication because this can exacerbate associated disability, (2) maintain an open mind and reassess the diagnosis if the clinical presentation changes, and (3) understand and communicate to the family that pain has a biologic basis (likely related to neural signaling and neurotransmitter dysregulation), and the pain is naturally distressing to the child and family. All patients and families should receive a simple explanation of pain physiology that helps them understand the importance of (1) functional rehabilitation to normalize pain signaling, (2) the low risk of causing further injury with systematic increases in normal functioning, and (3) the likely failure of treatment if pain is managed as if it were acute. Because it is counterintuitive for most people to move a part of the body that hurts, many patients with chronic pain have atrophy or contractures of a painful extremity from disuse. Additionally, associated increases in worry and anxiety may exacerbate pain and leave the body even more vulnerable to further illness, injury, and disability. Pain can have a significant impact on many areas of normal functioning and routine for children, and school absenteeism and related consequences of missed schooling are often significant problems. Appropriate assessment and evaluation of the child with chronic pain and the child's family is the critical first step necessary in developing a treatment plan.

Interdisciplinary pediatric pain programs have become the standard of care for treating complex chronic pain problems in youth. In recognition of the severity and complexity of pain and disability for some children, different settings and treatment delivery models for providing pain care have been explored. One option is inpatient and day hospital treatment programs. They often address barriers to access to outpatient treatment and coordination of care. In addition, they provide an intensive treatment option for children who do not make adequate progress in outpatient treatment or who are severely disabled by pain. Early programs developed in the 1990s focused on treatment of CRPS through intensive inpatient rehabilitation and exercise-based treatment programs. Later developing programs expanded to other clinical populations and expanded the treatment focus to incorporate a range of rehabilitation and psychologic therapies delivered both individually and in groups. The typical length of inpatient admissions for children with chronic pain in such programs is 3-4 wk and there is emerging evidence to suggest benefit from these programs.

Another intervention delivery option is remote management, referring to pain interventions utilized outside of the clinic/hospital setting to reach children in their homes or communities. Interventions are typically delivered using some form of technology, such as the Internet, or may rely on other media such as telephone counseling or use of written self-help materials. Most typically, remote management of pain includes monitoring, counseling, and/or delivery of behavioral and CBT interventions. Internet interventions have received the most research attention to date with published examples for several different pediatric chronic pain conditions with promising findings for pain reduction. Telemedicine, while in widespread use clinically for many pediatric health conditions, has not yet been formally evaluated in pediatric pain. Within any community, the pediatrician will need to locate appropriate referral sources for patients with complex chronic pain.

Chapter 63

Poisoning

Mark A. Kostic

Poisoning is now the number 1 cause of injury death in the United States, even surpassing that from motor vehicle collisions. The majority of these deaths are unintentional (i.e., not suicide). In adolescents, poisoning is the third leading cause of injury-related death. Of the more than 2 million human poisoning exposures reported annually to the National Poison Data Systems of the American Association of Poison Control Centers, approximately 50% occur in children younger than 6 yr old. Almost all of these exposures are unintentional and reflect the propensity for young children to put virtually anything in their mouths. Fortunately, children younger than 6 yr account for <2% of all poisoning fatalities reported to National Poison Data Systems.

More than 90% of toxic exposures in children occur in the home, and most involve only a single substance. Ingestion accounts for the vast majority of exposures, with a minority occurring via the dermal, inhalational, and ophthalmic routes. Approximately 50% of cases involve nondrug substances, such as cosmetics, personal care items, cleaning solutions, plants, and foreign bodies. Pharmaceutical preparations account for the remainder of exposures, and analgesics, topical preparations, cough and cold products, and vitamins are the most commonly reported categories.

The majority of poisoning exposures in children younger than 6 yr can be managed without direct medical intervention (beyond a call to

Table 63-1 Common Agents Potentially Toxic to Young Children (<6 yr) in Small Doses*

SUBSTANCE	TOXICITY
Aliphatic hydrocarbons (e.g., gasoline, kerosene, lamp oil)	Acute lung injury
Antimalarials (chloroquine, quinine)	Seizures, dysrhythmias
Benzocaine	Methemoglobinemia
β Blockers (lipid-soluble β blockers [e.g., propranolol] are more toxic than water-soluble β blockers [e.g., atenolol])	Bradycardia, hypotension
Calcium channel blockers	Bradycardia, hypotension, hyperglycemia
Camphor	Seizures
Caustics (pH <2 or >12)	Airway, esophageal and gastric burns
Clonidine	Lethargy, bradycardia, hypotension
Diphenoxylate and atropine (Lomotil)	CNS depression, respiratory depression
Hypoglycemics, oral (sulfonylureas and meglitinides)	Hypoglycemia, seizures
Laundry detergent packets (pods)	Airway issues, respiratory distress, altered mental status
Lindane	Seizures
Monoamine oxidase inhibitors	Hypertension followed by delayed cardiovascular collapse
Methyl salicylate	Tachypnea, metabolic acidosis, seizures
Opioids (especially methadone, buprenorphine)	CNS depression, respiratory depression
Organophosphate pesticides	Cholinergic crisis
Phenothiazines (especially chlorpromazine, thioridazine)	Seizures, dysrhythmias
Theophylline	Seizures, dysrhythmias
Tricyclic antidepressants	CNS depression, seizures, dysrhythmias, hypotension

*"Small dose" typically implies 1 or 2 pills or 5 mL.
CNS, central nervous system.

the regional poison control center), either because the product involved is not inherently toxic or the quantity of the material involved is not sufficient to produce clinically relevant toxic effects. However, a number of substances are potentially highly toxic to toddlers in small doses (Table 63-1). In 2012, carbon monoxide and analgesics (acetaminophen and salicylate) were the leading causes of poison-related fatalities in young children (<6 yr). In addition, prescription opioids, antidepressants, cardiovascular drugs, and aliphatic hydrocarbons were significant causes of mortality.

Poison prevention education should be an integral part of all well-child visits, starting at the 6 mo visit. Counseling parents and other caregivers about potential poisoning risks, how to poison-proof a child's environment, and what to do if an ingestion or exposure occurs diminishes the likelihood of serious morbidity or mortality. Poison prevention education materials are available from the American Academy of Pediatrics and regional poison control centers. A network of poison control centers exists in the United States, and anyone at any time can contact a regional poison center by calling this toll-free number: **1-800-222-1222**. Parents should be encouraged to share this number with grandparents, relatives, babysitters, and any other caregivers.

Product safety measures, poison prevention education, early recognition of exposures, and around-the-clock access to regionally based poison control centers all contribute to the favorable outcomes in young children. Poisoning exposures in children 6-12 yr old are much less common, involving only approximately 6% of all reported pediatric exposures. A second peak in pediatric exposures occurs in adolescence. Exposures in the adolescent age group are primarily intentional (suicide or abuse or misuse of substances) and thus often result in more severe toxicity (see Chapter 114). Families should be informed and given anticipatory guidance that nonprescription and prescription medications, and even household products (e.g., inhalants), are common sources of adolescent exposures. Adolescents (ages 13-19 yr) accounted for 45 of the 73 poison-related pediatric deaths in 2012 reported to National Poison Data System (4% of all fatalities called in to poison centers). Pediatricians should be aware of the signs of drug abuse or suicidal ideation in this population and should aggressively intervene (see Chapter 114).

PREVENTION

Deaths caused by unintentional poisoning among younger children have decreased dramatically over the past 2 decades, particularly among children younger than 5 yr of age. In 1970, when the Poison Packaging Prevention Act was passed, 226 poisoning deaths of children younger than age 5 yr occurred compared with only 21 in 2012. Poisoning prevention demonstrates the effectiveness of passive strategies, including the use of child-resistant packaging and limited doses per container. Difficulty using child-resistant containers by adults is an important cause of poisoning in young children today; in 18.5% of households in which poisoning occurred in children younger than 5 yr of age, the child-resistant closure was replaced, and 65% of the packaging used did not work properly. Nearly 20% of ingestions occur from drugs owned by grandparents, a group that has difficulty using traditional child-resistant containers.

Even though there has been success in preventing poisoning in young children, there has been a remarkable rise in poison-related death over the past 20 yr in the adolescent population. This has mirrored the ever-increasing rate of opioid prescriptions written by healthcare providers.

APPROACH TO THE POISONED PATIENT

The initial approach to the patient with a witnessed or suspected poisoning should be no different than that in any other sick child, starting with stabilization and rapid assessment of the airway, breathing, circulation, and mental status (see Chapter 67). In any patient with altered mental status, a serum dextrose concentration should be obtained early and naloxone administration should be considered. A targeted history and physical examination serves as the foundation for a thoughtful differential diagnosis, which can then be further refined through laboratory testing and other diagnostic studies.

INITIAL EVALUATION

History

Obtaining an accurate problem-oriented history is of paramount importance. Intentional poisonings (suicide attempts; abuse or misuse) are typically more severe than unintentional, exploratory ingestions. In patients without a witnessed exposure, historical features such as age of the child (toddler or adolescent), acute onset of symptoms without prodrome, sudden alteration of mental status, multiple system organ dysfunction, or high levels of household stress should suggest a possible diagnosis of poisoning.

Description of the Exposure

For household and workplace products, names (brand, generic, chemical) and specific ingredients, along with their concentrations, can often

be obtained from the labels. Poison control center specialists can also help to identify possible ingredients and review the potential toxicities of each component. In cases of suspected ingestion, poison center specialists can help identify pills based on markings, shape, and color. If referred to the hospital for evaluation, parents should be instructed to bring the products, pills, and/or containers with them to assist with identifying and quantifying the exposure. If a child is found with an unknown pill in the child's mouth, the history must include a list of all medications in the child's environment (including medications that grandparents, parents, siblings, caregivers, or other visitors might have brought into the house). In the case of an unknown exposure, clarifying where the child was found (e.g., garage, kitchen, laundry room, bathroom, backyard, workplace) can help to generate a list of potential toxins.

Next, it is important to clarify the timing of the ingestion and to obtain some estimate of how much of the substance was ingested. It is better to overestimate the amount ingested to prepare for the worst-case scenario. Counting pills or measuring the remaining volume of a liquid ingested can sometimes be useful in generating estimates. For inhalational, ocular, or dermal exposures, the concentration of the agent and the length of contact time with the material should be determined if possible.

Symptoms

Obtaining a description of symptoms experienced after ingestion, including their timing of onset relative to the time of ingestion and their progression, can generate a list of potential toxins and to predict the severity of the ingestion. Coupled with physical exam findings, reported symptoms assist practitioners in identifying *toxidromes* or recognized poisoning syndromes suggestive of poisoning from specific substances or classes of substances (Tables 63-2, 63-3, and 63-4).

Past Medical History

Underlying diseases can make a child more susceptible to the effects of a toxin. Concurrent drug therapy can also increase susceptibility because certain drugs may interact with the toxin. Pregnancy is a common precipitating factor in adolescents' suicide attempts and can influence both evaluation of the patient and subsequent treatment. A history of psychiatric illness can make patients more prone to substance abuse, misuse, intentional ingestions, and polypharmacy complications. A developmental history is important to ensure that the history provided is appropriate for the child's developmental stage (e.g., a report of a 6 mo old picking up a large container of laundry detergent and drinking it should raise a red flag).

Social History

Understanding the child's social environment helps to identify potential sources of exposures (caregivers, visitors, grandparents, recent parties or social gatherings) and environmental stressors (new baby, parent's illness, financial stress) that might have contributed to the ingestion. Unfortunately, some poisonings occur in the setting of serious neglect or intentional abuse.

Physical Examination

A targeted physical exam is important to identifying the potential toxin and assessing the severity of the exposure. Initial efforts should be directed toward assessing and stabilizing the airway, breathing, circulation, and mental status. Once one has ensured that the airway is secure and the patient is stable from a cardiopulmonary standpoint, a more extensive physical exam can help to identify characteristics of specific toxins or classes of toxins.

In the poisoned patient, the key features of the physical exam are the vital signs, mental status, pupils (size, reactivity) nystagmus, skin, bowel sounds, and odors. These findings might suggest a toxidrome that can guide the differential diagnosis and initial management.

Laboratory Evaluation

For select intoxications (e.g., salicylates, some anticonvulsants, acetaminophen, iron, digoxin, methanol, lithium, ethylene glycol, carbon monoxide, lead), quantitative blood concentrations are integral to confirming the diagnosis and formulating a treatment plan. For most exposures, quantitative measurement is not readily available and is not likely to alter management. All intoxicant levels must be interpreted in conjunction with the history. For instance, a methanol level of 20 mg/dL 1 hr after ingestion may well be nontoxic, whereas a similar level 24 hr after ingestion implies a patient with significant poisoning. In general, patients with multiple or chronic exposures to a drug or other chemical will be more symptomatic at lower drug levels than those with a single exposure.

Both urine drug-of-abuse screens and the more comprehensive drug screens vary widely in their ability to detect toxins and generally add little information to the clinical assessment, particularly if the agent is known and the patient's symptoms are consistent with that agent. If a drug screen is ordered, it is important to know that the components screened for, and the lower limits of detection, vary from laboratory to laboratory. In addition, the interpretation of most drug screens is hampered by false-positive and false-negative results; standard urine opiate screens will not be positive after exposure to a synthetic opioid (e.g., methadone, buprenorphine, fentanyl). The urine drug-of-abuse screen is typically of limited utility when it comes to medical clearance, but does serve a useful function for psychiatrists in their evaluation of the adolescent patient. Apart from its psychiatric usefulness, urine drug-of-abuse screens are potentially helpful in patients with altered mental status of unknown etiology, persistent, unexplained tachycardia, acute myocardial ischemia or stroke at a young age, and in the assessment of a neglected or abused child. Consultation with a medical toxicologist can be helpful in interpreting drug screens and ordering specific drug levels or metabolites that can aid in patient management.

In the case of a neglected or allegedly abused child, a positive toxicology screen can add substantial weight to a claim of abuse or neglect. In these cases and any case with medicolegal implications, any positive screen *must* be confirmed with gas chromatography/mass spectroscopy, which is considered the gold standard measurement for legal purposes.

Acetaminophen is a widely available medication and a commonly detected coingestant with the potential for severe toxicity. There is an effective antidote to acetaminophen poisoning that is time-dependent. Given that patients might initially be asymptomatic and might not report acetaminophen as a coingestant, an acetaminophen level should be checked in all patients who present after an intentional exposure or ingestion. A basic chemistry panel (electrolytes, renal function, glucose) is necessary for all poisoned or potentially poisoned patients. Any patient with acidosis (a low serum bicarbonate level on the serum chemistry panel), must have an anion gap calculated because of the more specific differential diagnoses associated with an elevated anion gap metabolic acidosis. Patients with a known overdose of acetaminophen should have their liver transaminases assessed, as well as an INR (international normalized ratio). A serum creatine kinase level is indicated on any patient with a prolonged "down time" as rhabdomyolysis can result from laying supine on a hard surface without movement for just a few hours. Serum osmolality is only helpful as a surrogate marker for a toxic alcohol exposure if a serum concentration of the alcohol cannot be obtained in a reasonable time frame. A urine pregnancy test is, of course, mandatory for all adolescent female patients. Based on the clinical presentation and the presumed poison, additional lab tests may also be helpful (Table 63-5).

Additional Diagnostic Testing

An electrocardiogram (ECG) is a quick and noninvasive bedside test that can yield important clues to diagnosis and prognosis. Toxicologists pay particular attention to the ECG intervals (Table 63-6). A widened QRS interval, putting the patient at risk for monomorphic ventricular tachycardia, suggests blockade of fast sodium channels, and may be seen after ingestion of tricyclic antidepressants, diphenhydramine, and cocaine, among others. A widened QTc interval suggests effects at the potassium rectifier channels and portends a risk of torsades de pointes (polymorphic ventricular tachycardia).

Table 63-2 Selected Historical and Physical Findings in Poisoning

SIGN	TOXIN
ODOR	
Bitter almonds	Cyanide
Acetone	Isopropyl alcohol, methanol, paraldehyde, salicylates
Alcohol	Ethanol
Wintergreen	Methyl salicylate
Garlic	Arsenic, thallium, organophosphates, selenium
OCULAR SIGNS	
Miosis	Opioids (except propoxyphene, meperidine, and pentazocine), organophosphates and other cholinergics, clonidine, phenothiazines, sedative–hypnotics, olanzapine
Mydriasis	Anticholinergics (e.g., antihistamines, TCAs, atropine), sympathomimetics (cocaine, amphetamines, PCP) postanoxic encephalopathy, opiate withdrawal
Nystagmus	Anticonvulsants, sedative–hypnotics, alcohols, PCP, ketamine, dextromethorphan
Lacrimation	Organophosphates, irritant gas or vapors
Retinal hyperemia	Methanol
CUTANEOUS SIGNS	
Diaphoresis	Cholinergics (organophosphates), sympathomimetics, withdrawal syndromes
Alopecia	Thallium, arsenic
Erythema	Boric acid, elemental mercury, cyanide, carbon monoxide, disulfiram, scombroid, anticholinergics, vancomycin
Cyanosis (unresponsive to oxygen)	Methemoglobinemia (e.g., benzocaine, dapsone, nitrites, phenazopyridine), amiodarone, silver
ORAL SIGNS	
Salivation	Organophosphates, salicylates, corrosives, ketamine, PCP, strychnine
Oral burns	Corrosives, oxalate-containing plants
Gum lines	Lead, mercury, arsenic, bismuth
GASTROINTESTINAL SIGNS	
Diarrhea	Antimicrobials, arsenic, iron, boric acid, cholinergics, colchicine, opioid withdrawal
Hematemesis	Arsenic, iron, caustics, NSAIDs, salicylates
Constipation	Lead
CARDIAC SIGNS	
Tachycardia	Sympathomimetics, anticholinergics, antidepressants, antipsychotics, methylxanthines (theophylline, caffeine), salicylates, cellular asphyxiants (cyanide, carbon monoxide, hydrogen sulfide), withdrawal (ethanol, sedatives, clonidine, opioids), serotonin syndrome, neuroleptic malignant syndrome
Bradycardia	β Blockers, calcium channel blockers, digoxin, clonidine, organophosphates, opioids, sedative–hypnotics
Hypertension	Sympathomimetics, anticholinergics, monoamine oxidase inhibitors, serotonin syndrome, neuroleptic malignant syndrome, clonidine withdrawal
Hypotension	β Blockers, calcium channel blockers, cyclic antidepressants, iron, antipsychotics, barbiturates, clonidine, opioids, arsenic, amatoxin mushrooms, cellular asphyxiants (cyanide, carbon monoxide, hydrogen sulfide), snake envenomation
RESPIRATORY SIGNS	
Depressed respirations	Opioids, sedative-hypnotics, alcohol, clonidine, barbiturates
Tachypnea	Salicylates, sympathomimetics, caffeine, metabolic acidosis, carbon monoxide, hydrocarbon aspiration
CENTRAL NERVOUS SYSTEM SIGNS	
Ataxia	Alcohols, anticonvulsants, sedative–hypnotics, lithium, dextromethorphan, carbon monoxide, inhalants
Coma	Opioids, sedative–hypnotics, anticonvulsants, antidepressants, antipsychotics, ethanol, anticholinergics, clonidine, GHB, alcohols, salicylates, barbiturates
Seizures	Sympathomimetics, anticholinergics, antidepressants (especially TCAs, bupropion, venlafaxine), cholinergics (organophosphates), isoniazid, camphor, lindane, salicylates, lead, nicotine, tramadol, water hemlock, withdrawal
Delirium/psychosis	Sympathomimetics, anticholinergics, LSD, PCP, hallucinogens, lithium, dextromethorphan, steroids, withdrawal
Peripheral neuropathy	Lead, arsenic, mercury, organophosphates

GHB, γ-hydroxybutyrate; LSD, lysergic acid diethylamide; NSAID, nonsteroidal antiinflammatory drug; PCP, phencyclidine; TCA, tricyclic antidepressant.

Chest x-ray may reveal signs of pneumonitis (e.g., hydrocarbon aspiration), noncardiogenic pulmonary edema (e.g., salicylate toxicity), or a foreign body. Abdominal x-ray is most helpful in screening for the presence of lead paint chips or other foreign bodies. It may detect a bezoar, demonstrate radiopaque tablets, or reveal drug packets in a body packer. Upper endoscopy may be useful for prognosis after significant caustic ingestions. Further diagnostic testing is based on the differential diagnosis and pattern of presentation.

PRINCIPLES OF MANAGEMENT

The principles of management of the poisoned patient are supportive care, antidotes, decontamination, and enhanced elimination. Few patients meet criteria for all of these interventions, though clinicians should consider each option in every poisoned patient so as not to miss a potentially lifesaving therapy. Antidotes are available for relatively few poisons (Table 63-7), thus emphasizing the importance of meticulous supportive care and close clinical monitoring.

Poison control center staff are specifically trained to provide expertise in the management of poisoning exposures. Parents should be instructed to call the poison control center (**1-800-222-1222**) for any concerning exposure. Poison specialists can assist parents in assessing the potential toxicity and severity of the exposure; they can further determine which children can be safely monitored at home and which children should be referred to the emergency department for further

Table 63-3 Recognizable Poison Syndromes ("Toxidromes")

TOXIDROME	SIGNS: VITAL SIGNS	MENTAL STATUS	PUPILS	SKIN	BOWEL SOUNDS	OTHER	POSSIBLE TOXINS
Sympathomimetic	Hypertension, tachycardia, hyperthermia	Agitation, psychosis, delirium, violence	Dilated	Diaphoretic	Normal to increased		Amphetamines, cocaine, PCP, bath salts (cathinones), ADHD medication
Anticholinergic	Hypertension, tachycardia, hyperthermia	Agitated, delirium, coma, seizures	Dilated	Dry, hot	Diminished	Ileus urinary retention	Antihistamines, tricyclic antidepressants, atropine, jimson weed
Cholinergic	Bradycardia BP and temp typically normal	Confusion, coma, fasciculations	Small	Diaphoretic	Hyperactive	Diarrhea, urination, bronchorrhea, bronchospasm, emesis, lacrimation, salivation	Organophosphates (insecticides, nerve agents), carbamates (physostigmine, neostigmine, pyridostigmine) Alzheimer medications, myasthenia treatments
Opioids	Respiratory depression bradycardia, hypotension, hypothermia	Depression, coma, euphoria	Pinpoint	Normal	Normal to decreased		Methadone, buprenorphine, morphine, oxycodone, heroin, etc.
Sedative–hypnotics	Respiratory depression, HR normal to decreased, BP normal to decreased, temp normal to decreased	Somnolence, coma	Small or normal	Normal	Normal		Barbiturates, benzodiazepines, ethanol
Serotonin syndrome (similar findings with neuroleptic malignant syndrome)	Hyperthermia, tachycardia, hypertension or hypotension (autonomic instability)	Agitation, confusion, coma	Dilated	Diaphoretic	Increased	Neuromuscular hyperexcitability: clonus, hyperreflexia (lower extremities > upper extremities)	SSRIs, lithium, MAOIs, linezolid, tramadol, meperidine, dextromethorphan
Salicylates	Tachypnea, hyperpnea, tachycardia, hyperthermia	Agitation, confusion, coma	Normal	Diaphoretic	Normal	Nausea, vomiting, tinnitus, ABG with primary respiratory alkalosis and primary metabolic acidosis; tinnitus or difficulty hearing	Aspirin and aspirin-containing products, methyl-salicylate
Withdrawal (sedative–hypnotic)	Tachycardia, tachypnea, hyperthermia	Agitation, tremor, seizure, hallucinosis, delirium tremens	Dilated	Diaphoretic	Increased		Lack of access to ethanol, benzodiazepines, barbiturates, GHB, or excessive use of flumazenil
Withdrawal (opioid)	Tachycardia	Restlessness, anxiety	Dilated	diaphoretic	Hyperactive	Nausea, vomiting, diarrhea	Lack of access to opioids or excessive use of naloxone

ABG, arterial blood gas; ADHD, attention-deficit/hyperactivity disorder; BP, blood pressure; GHB, γ-hydroxybutyrate; HR, heart rate; MAOI, monoamine oxidase inhibitor; PCP, phencyclidine; SSRI, selective serotonin reuptake inhibitor; temp, temperature.

Table 63-4 Mini-Toxidromes

TOXIDROMES	SYMPTOMS AND SIGNS	EXAMPLES
α_1 Antagonists	CNS depression, tachycardia, miosis	Chlorpromazine, quetiapine, clozapine, olanzapine, risperidone
α_2 Agonist	CNS depression, bradycardia, hypertension (early), hypotension (late), miosis	Clonidine, oxymetazoline, tetrahydrozoline, tizanidine
Clonus/myoclonus	CNS depression, myoclonic jerks, clonus, hyperreflexia	Carisoprodol, lithium, serotonergic agents, bismuth, organic lead, organic mercury
Sodium channel blockers	CNS toxicity, wide QRS	Cyclic antidepressants and structurally related agents, propoxyphene, quinidine/quinine, amantadine, antihistamines, bupropion, cocaine
Potassium channel blockers	CNS toxicity, long QT	Butyrophenones, methadone, phenothiazines, ziprasidone

CNS, central nervous system.

QTc PROLONGATION* Amiodarone Antipsychotics (typical and atypical) Arsenic Cisapride Citalopram and other SSRIs Clarithromycin, erythromycin Disopyramide, dofetilide, ibutilide Fluconazole, ketoconazole, itraconazole Methadone Pentamidine Phenothiazines Sotalol

*This is a select list of important toxins, other medications are also associated with QTc prolongation.
SSRI, selective serotonin reuptake inhibitor.

evaluation and care. Ninety percent of all exposures in children younger than 6 yr of age called into poison centers are managed at home. The American Academy of Clinical Toxicology has generated consensus statements for out-of-hospital management of common ingestions (e.g., acetaminophen, iron, calcium channel blockers) that serve to guide poison center recommendations regarding whom to refer to an emergency department. Up to a third of calls to poison centers involve hospitalized patients.

SUPPORTIVE CARE

Careful attention is paid first to the "ABCs" of airway, breathing and circulation; there should be a low threshold to aggressively manage the airway of a poisoned patient because of the patient's propensity to

Table 63-7 Common Antidotes for Poisoning

POISON	ANTIDOTE	DOSAGE	ROUTE	ADVERSE EFFECTS, WARNINGS, COMMENTS
Acetaminophen	*N*-Acetylcysteine (Mucomyst)	140 mg/kg loading, followed by 70 mg/kg q4h	PO	Vomiting (patient-tailored regimens are the norm)
	N-Acetylcysteine (Acetadote)	150 mg/kg over 1 hr, followed by 50 mg/kg over 4 hr, followed by 100 mg/kg over 16 hr	IV	Anaphylactoid reactions (most commonly seen with loading dose) (Higher doses of the infusion are often recommended depending upon the acetaminophen level and the degree of injury)
Anticholinergics	Physostigmine	0.02 mg/kg over 5 min; may repeat q5-10min to 2 mg max	IV/IM	Bradycardia, seizures, bronchospasm *Note:* Do not use if conduction delays on ECG
Benzodiazepines	Flumazenil	0.2 mg over 30 sec; if response is inadequate, repeat q1min to 1 mg max	IV	Agitation, seizures; **do not use for unknown ingestions**
β Blockers	Glucagon	0.15 mg/kg bolus followed by infusion of 0.05-0.15 mg/kg/hr	IV	Hyperglycemia, vomiting
Calcium channel blockers	Insulin	1 unit/kg bolus followed by infusion of 0.5-1 unit/kg/hr	IV	Hypoglycemia Follow serum potassium and glucose closely
	Calcium salts	Dose depends on the specific calcium salt	IV	
Carbon monoxide	Oxygen	100% F_{IO_2} via non–rebreather mask (or ET if intubated)	Inhalational	Some patients may benefit from hyperbaric oxygen (see text)
Cyanide	Cyanide kit:			
	Amyl nitrate	1 crushable ampule; inhale 30 sec of each min	Inhalation	Methemoglobinemia
	Sodium nitrate	0.33 mL/kg of 3% solution if hemoglobin level is not known; otherwise, based on tables with product	IV	Methemoglobinemia Hypotension
	Sodium thiosulfate	1.6 mL/kg of 25% solution; may be repeated q30-60min to max of 50 mL	IV	If inducing methemoglobinemia is contraindicated; consider only using the thiosulfate component of the kit
	Hydroxocobalamin (Cyanokit)	70 mg/kg (adults: 5 g) given over 15 min	IV	Flushing/erythema, nausea, rash, chromaturia, hypertension, headache
Digitalis	Digoxin-specific Fab antibodies (Digibind; DigiFab)	1 vial binds 0.6 mg of digitalis glycoside; #vials = digitalis level × weight in kg/100	IV	Allergic reactions (rare), return of condition being treated with digitalis glycoside
Ethylene glycol, methanol	Fomepizole	15 mg/kg load; 10 mg/kg q12h × 4 doses; 15 mg/kg q12h until EG level is <20 mg/dL	IV	Infuse slowly over 30 min; If fomepizole is not available, can treat with oral ethanol (80 proof)
Iron	Deferoxamine	Infusion of 5-15 mg/kg/hr (max: 6 g/24 hr)	IV	Hypotension (minimized by avoiding rapid infusion rates)
Isoniazid (INH)	Pyridoxine	Empirical dosing: 70 mg/kg (max dose = 5 g) If ingested dose is known: 1 g per gram of INH	IV	May also be used for *Gyromitra* mushroom ingestions
Lead and other heavy metals (e.g., arsenic, inorganic mercury)	BAL (dimercaprol)	3-5 mg/kg/dose q4hr, for the 1st day; subsequent dosing depends on the toxin	Deep IM	Local injection site pain and sterile abscess, vomiting, fever, salivation, nephrotoxicity *Caution:* prepared in peanut oil; contraindicated in patients with peanut allergy
	Calcium disodium EDTA	35-50 mg/kg/day × 5 days; may be given as a continuous infusion or 2 divided doses/day	IV	Vomiting, fever, hypertension, arthralgias, allergic reactions, local inflammation, nephrotoxicity (maintain adequate hydration, follow UA and renal function)
	Dimercaptosuccinic acid (succimer, DMSA, Chemet)	10 mg/kg/dose q8h × 5 days, then 10 mg/kg q12h × 14 days	PO	Vomiting, hepatic transaminase elevation, rash

Continued

Table 63-7 Common Antidotes for Poisoning—cont'd

POISON	ANTIDOTE	DOSAGE	ROUTE	ADVERSE EFFECTS, WARNINGS, COMMENTS
Methemoglobinemia	Methylene blue, 1% solution	0.1-0.2 mL/kg (1-2 mg/kg) over 5-10 min; may be repeated q30-60min	IV	Vomiting, headache, dizziness, blue discoloration of urine
Opioids	Naloxone	0.01-0.1 mg/kg; adolescents/adults: 0.04-2 mg, repeated as needed; may give continuous infusion	IV	Acute withdrawal symptoms if given to addicted patients May also be useful for clonidine ingestions (inconsistent response)
Organophosphates	Atropine Pralidoxime (2-PAM)	0.05-0.1 mg/kg repeated q5-10min as needed 25-50 mg/kg over 5-10 min (max: 200 mg/min); can be repeated after 1-2 hr, then q10-12hr as needed	IV/ET IV/IM	Tachycardia, dry mouth, blurred vision, urinary retention Nausea, dizziness, headache, tachycardia, muscle rigidity, bronchospasm (rapid administration)
Salicylates	Sodium bicarbonate	Bolus 1-2 mEq/kg followed by a continuous infusion	IV	Follow potassium closely and replete as necessary Goal urine pH 7.5-8.0
Sulfonylureas	Octreotide and dextrose	1-2 μg/kg/dose (adults 50-100 μg) q6-8hr	IV/SC	
Tricyclic antidepressants	Sodium bicarbonate	Bolus 1-2 mEq/kg; repeated bolus dosing as needed to keep QRS <110 msec	IV	Indications: QRS widening (≥110 ms), hemodynamic instability; follow potassium

BAL, British antilewisite; DMSA, dimercaptosuccinic acid; ECG, electrocardiogram; FIO2, fraction of inspired oxygen; EDTA, ethylenediaminetetraacetic acid; EG, ethylene glycol; ET, endotracheal tube; max, maximum; UA, urinalysis.

quickly become comatose. In fact, endotracheal intubation is often the only significant intervention needed in many poisoned patients, especially those poisoned with neuroleptics. An important caveat is with the tachypneic patient with a clear lung exam and normal oxygen saturation. This should alert the clinician to the likelihood that the patient is compensating for an acidemia. Paralyzing such a patient and underventilating them might prove fatal. If intubation is absolutely necessary for airway protection or a tiring patient, a good rule of thumb is to match the ventilatory settings to the patient's preintubation minute ventilation.

In the hypotensive patient, it should be remembered that these patients often are not hypovolemic, but are poisoned; aggressive fluid resuscitation may lead to fluid overload. If hypotension persists after 1 or 2 standard boluses of crystalloid, infusion of a direct-acting vasopressor, such as norepinephrine or epinephrine, is preferred. Dysrhythmias are managed in the standard fashion apart from those caused by agents that block the fast sodium channels of the heart for which sodium bicarbonate therapy is utilized.

Seizures are primarily managed with agents that potentiate the γ-aminobutyric acid complex, such as benzodiazepines or barbiturates. Creatinine kinase levels should be drawn on any patient found unconscious. The goal of supportive therapy is to support the patient's vital functions until the patient can eliminate the toxin.

Antidotes

Antidotes are available for relatively few toxins (see Tables 63-7 and 63-8), but early and appropriate use of an antidote is a key element in managing the poisoned patient.

Decontamination

The majority of poisonings in children are from ingestion, although exposures can also occur via inhalational, dermal, and ocular routes. The goal of decontamination is to minimize absorption of the toxic substance. The specific method employed depends on the properties of the toxin itself and the route of exposure. Regardless of the decontamination method used, the efficacy of the intervention decreases with increasing time since exposure. *Decontamination should not be routinely employed for every poisoned patient.* Instead, careful decisions regarding the utility of decontamination should be made for each patient and should include consideration of the toxicity and pharmacologic properties of the exposure, the route of the exposure, the time since the exposure, and the risks vs the benefits of the decontamination method.

Table 63-8 Additional Antidotes

ANTIDOTES	TOXIN OR POISON
Latrodectus antivenin	Black widow spider
Botulinum antitoxin	Botulinum toxin
Insulin and glucose	Calcium channel antagonists
Diphenhydramine and/or benztropine	Dystonic reactions
Calcium salts	Fluoride, calcium channel blockers
Protamine	Heparin
Folinic acid	Methotrexate, trimethoprim, pyrimethamine
Crotalidae-specific Fab antibodies	Rattlesnake envenomation
Sodium bicarbonate	Sodium channel blockade (tricyclic antidepressants, type 1 antiarrhythmics)

Dermal and ocular decontamination begin with removal of any contaminated clothing and particulate matter, followed by flushing of the affected area with tepid water or normal saline. Treating clinicians should wear proper protective gear when performing irrigation. Flushing for a minimum of 10-20 minutes is recommended for most exposures, although some chemicals (e.g., alkaline corrosives) require much longer periods of flushing. Dermal decontamination, especially after exposure to adherent or lipophilic (e.g., organophosphates) agents, should include thorough cleansing with soap and water. Water should *not* be used for decontamination after exposure to highly reactive agents, such as elemental sodium, phosphorus, calcium oxide, and titanium tetrachloride. After an inhalational

exposure, decontamination involves moving the patient to fresh air and administering supplemental oxygen if indicated.

Gastrointestinal (GI) decontamination is a controversial topic among medical toxicologists. *GI decontamination strategies are most likely to be effective in the 1st hour after an acute ingestion*. GI absorption may be delayed after ingestion of agents that slow GI motility (anticholinergic medications, opioids), massive pill ingestions, sustained-release preparations, and ingestions of agents that can form pharmacologic bezoars (e.g., enteric-coated salicylates). GI decontamination at more than 1 hr after ingestion may be considered in patients who ingest toxic substances with these properties. Even rapid institution of GI decontamination with activated charcoal will, at best, bind only approximately 30% of the ingested substance. GI decontamination should never supplant excellent supportive care and should not be employed in an unstable or persistently vomiting patient. Described methods of GI decontamination include induced emesis with ipecac, gastric lavage, cathartics, activated charcoal, and whole-bowel irrigation (WBI). Of these, only activated charcoal and WBI are likely to be of clinical benefit.

Syrup of Ipecac

Syrup of ipecac contains 2 emetic alkaloids that work in both the central nervous system (CNS) and locally in the GI tract to produce vomiting. In the 1960s, the American Academy of Pediatrics lobbied for nonprescription availability of ipecac and in the 1980s recommended that ipecac be given to parents at the 6 mo well-child check, coupled with a discussion about poison prevention strategies. Since then, studies have failed to document a significant clinical impact from the use of ipecac and have documented multiple adverse events from its use. After a review of the evidence and assessment of the risks and benefits of ipecac use, the American Academy of Pediatrics, the American Academy of Clinical Toxicology, and the American Association of Poison Control Centers have all published statements in favor of **abandoning the use of ipecac.**

Gastric Lavage

Gastric lavage involves placing a tube into the stomach to aspirate contents, followed by flushing with aliquots of fluid, usually water or normal saline. Although gastric lavage was used routinely for many years, objective data do not document or support clinically relevant efficacy. This is particularly true in children, in whom only small-bore tubes can be used. Lavage is time-consuming and painful, and can induce bradycardia via a vagal response to tube placement. It can delay administration of more definitive treatment (activated charcoal), and under the best circumstances only removes a fraction of gastric contents. *Thus, in most clinical scenarios, the use of gastric lavage is no longer recommended.*

Single-Dose Activated Charcoal

Activated charcoal is thought to be a potentially useful method of GI decontamination, although clinical data to support this claim is limited. Charcoal is "activated" via heating to extreme temperatures, creating an extensive network of pores that provides a very large adsorptive surface area. Many, but not all, toxins are adsorbed onto its surface, thus preventing absorption from the GI tract. *Charcoal is most likely to be effective when given within 1 hr of ingestion.* Charged molecules (i.e., heavy metals, lithium, iron) and liquids do not bind well to activated charcoal (Table 63-9). Charcoal administration should also be avoided after ingestion of a caustic substance, because the presence of charcoal can impede subsequent endoscopic evaluation. A repeat dose of activated charcoal may be warranted in the cases of ingestion of an extended release product or, more commonly, with a significant salicylate poisoning as a result of its delayed and erratic absorption pattern.

The dose of activated charcoal is 1 g/kg in children or 50-100 g in adolescents and adults. Before administering charcoal, one *must* ensure that the patient's airway is intact or protected and that the patient has a benign abdominal exam. In the awake, uncooperative adolescent or child who refuses to drink the activated charcoal, there is relatively little utility and potential morbidity associated with forcing activated charcoal down a nasogastric tube, and such practice should be avoided. Approximately 20% of children vomit after receiving a dose of charcoal, emphasizing the importance of an intact airway and avoiding administration of charcoal after ingestion of substances that are particularly toxic when aspirated (e.g., hydrocarbons). If charcoal is given through a gastric tube in an intubated patient, placement of the tube should be carefully confirmed before activated charcoal is given because instillation of charcoal directly into the lungs can have disastrous effects. Constipation is another common side effect of activated charcoal, and in rare cases, bowel perforation has been reported.

In young children, practitioners may attempt to improve palatability by adding flavorings (chocolate or cherry syrup) or giving the mixture over ice cream. Cathartics (sorbitol, magnesium sulfate, magnesium citrate) have been used in conjunction with activated charcoal to prevent constipation and accelerate evacuation of the charcoal–toxin complex. There are no data demonstrating their value and there are numerous reports of adverse effects from cathartics. Cathartics should be used with care in young children and should never be used in multiple doses because of the risk of dehydration and electrolyte imbalance.

Table 63-9	Substances Poorly Adsorbed By Activated Charcoal
Alcohols	
Caustics: alkalis and acids	
Cyanide	
Heavy metals (e.g., lead)	
Hydrocarbons	
Iron	
Lithium	

Whole-Bowel Irrigation

WBI involves instilling large volumes (35 mL/kg/hr in children or 1-2 L/hr in adolescents) of a polyethylene glycol electrolyte solution (e.g., GoLYTELY) to "wash out" the entire GI tract. This technique may have some success after the ingestion of slowly absorbed substances (sustained-release preparations), substances not well adsorbed by charcoal (e.g., lithium, iron), transdermal patches, and drug packets. WBI can be combined with the use of activated charcoal, if appropriate (cocaine or heroin body packers). In children, WBI is of greatest utility in decontaminating the gut of a child whose abdominal X-ray demonstrates multiple lead paint chips. Careful attention should be paid to assessment of the airway and abdominal exam before initiating WBI, which should never be given to a patient without bowel sounds or with signs of obstruction or ileus, or without a protected airway. Given the rate of administration and volume needed to flush the system, WBI is typically administered via a nasogastric tube. WBI is continued until the rectal effluent is clear. Complications of WBI include vomiting, abdominal pain, and abdominal distention. Bezoar formation might respond to WBI but may also require endoscopy or surgery.

Enhanced Elimination

Enhancing excretion is only useful for a few toxins; in these cases, enhancing elimination is a potentially lifesaving intervention that results in improved clearance of a poison that has already been absorbed.

Urinary Alkalinization

A charged molecule, being polar and hydrophilic, does not easily cross a fat membrane. Such is the mechanism by which alkalinizing the urine enhances the elimination of some drugs that are weak acids by forming charged particles that are "trapped" within the renal tubules and thus excreted. Urinary alkalinization is accomplished via a continuous infusion of sodium bicarbonate–containing intravenous fluids, with a goal urine pH of 7.5-8. Alkalinization of the urine is most useful in managing salicylate and methotrexate toxicity.

Serum pH should be closely monitored because a serum pH of >7.55 is potentially dangerous to cellular functions. Other complications of

urinary alkalinization include electrolyte derangements, such as hypokalemia and hypocalcemia. This method of enhanced elimination is contraindicated in patients who are unable to tolerate the large volumes of fluid needed to achieve alkalinization, including patients with heart failure, kidney failure, pulmonary edema, or cerebral edema.

Hemodialysis

Few drugs or toxins are removed by dialysis in amounts sufficient to justify the risks and difficulty of dialysis. Toxins that are amenable to dialysis have the following properties: low volume of distribution (<1 L/kg), low molecular weight, low degree of protein binding, and high degree of water solubility. Examples of toxins for which dialysis may be useful include methanol, ethylene glycol, salicylates, theophylline, bromide, lithium, and, potentially, valproic acid. In addition to enhancing the elimination of the toxin itself, hemodialysis can also be useful to correct severe electrolyte disturbances and acid–base derangements resulting from the ingestion (e.g., metformin-associated lactic acidosis).

Multiple-Dose Activated Charcoal

Whereas single-dose activated charcoal is used as a method of decontamination, multiple doses of activated charcoal (MDACs) can help to enhance the elimination of some toxins. MDAC is typically given as 0.5 g/kg every 4-6 hr (for ≤24 hr) and continued until there is significant clinical improvement, including satisfactory decline of serum drug concentrations. MDACs enhance elimination via 2 proposed mechanisms: interruption of enterohepatic recirculation and "GI dialysis," which uses the intestinal mucosa as the dialysis membrane and pulls toxins from the bloodstream back into the intraluminal space, where they are adsorbed to the charcoal. The American Academy of Clinical Toxicology/European Association of Poisons Centres and Clinical Toxicologists position statement recommends MDAC in managing significant ingestions of carbamazepine, dapsone, phenobarbital, quinine, and theophylline. As with single-dose activated charcoal, contraindications to use of MDAC include an unprotected airway and a concerning abdominal exam (e.g., ileus, distention, peritoneal signs); thus the airway and abdominal exam *should be assessed before each dose.* A cathartic (e.g., sorbitol) may be given with the first dose, but it should not be used with subsequent doses owing to the risk of dehydration and electrolyte derangements. Although MDAC reduces the serum level of an intoxicant quicker than without MDAC, it has not been shown to have a significant impact on outcome.

Intralipid Emulsion Therapy

A potentially life-saving intervention of infusing Intralipid emulsions is a means of sequestering fat-soluble drugs and decreasing their impact at target organs. Initial experience regarding this intervention has been developed by anesthesiologists as a reversal agent for asystole resulting from inadvertent intravenous injection of bupivacaine. There are dozens of case reports published demonstrating the dramatic and rapid recovery of premorbid poisoned patients given a dose of Intralipid. Using the same 20% Intralipid used for total parenteral nutrition, a bolus dose of 1.5 mL/kg is given over 3 min, followed by an infusion of 0.25 mL/kg/min until recovery or a total of 10 mL/kg has been infused. Lipophilic drugs (LogP >2) are potentially bound by Intralipid emulsions, including calcium channel blockers (verapamil and diltiazem) and tricyclic antidepressants.

SELECTED COMPOUNDS COMMONLY INVOLVED IN PEDIATRIC POISONINGS

Herbal medicines (see Chapter 64), drugs of abuse (see Chapter 114), and environmental health hazards (see Chapters 718-725) are covered elsewhere.

Pharmaceuticals

Analgesics

Acetaminophen. Acetaminophen (APAP) is the most widely used analgesic and antipyretic in pediatrics, available in multiple formulations, strengths, and combinations. Consequently, APAP is commonly available in the home, where it can be unintentionally ingested by young children, taken in an intentional overdose by adolescents and adults, or inappropriately dosed in all ages. APAP toxicity remains the most common cause of acute liver failure in the United States, and is the number 1 cause of intentional poisoning death in the United States.

Pathophysiology. APAP toxicity results from the formation of a highly reactive intermediate metabolite, *N*-acetyl-*p*-benzoquinone imine. In therapeutic use, only a small percentage of a dose (approximately 5%) is metabolized by the hepatic cytochrome P450 enzyme CYP2E1 to *N*-acetyl-*p*-benzoquinone imine, which is then immediately conjugated with glutathione to form a nontoxic mercapturic acid conjugate. In overdose, glutathione stores are overwhelmed, and free *N*-acetyl-*p*-benzoquinone imine is able to combine with hepatic macromolecules to produce hepatocellular necrosis. The single acute toxic dose of APAP is generally considered to be >200 mg/kg in children and >7.5-10 g in adolescents and adults. Repeated administration of APAP at supratherapeutic doses (>90 mg/kg/day for consecutive days) can lead to hepatic injury or failure in some children, especially in the setting of fever, dehydration, poor nutrition, and other conditions that serve to reduce glutathione stores.

Any child with a history of acute ingestion of >200 mg/kg (unusual in children younger than 6 yr old) or with an acute intentional ingestion of any amount should be referred to a healthcare facility for clinical assessment and measurement of a serum APAP level.

Clinical and Laboratory Manifestations. Classically, 4 general stages of APAP toxicity have been described (Table 63-10). The initial signs are nonspecific (i.e., nausea and vomiting) and may not be present. Thus, the diagnosis of APAP toxicity cannot be based on clinical symptoms alone, but instead requires consideration of the combination of the patient's history, symptoms, and laboratory findings.

If a toxic ingestion is suspected, a serum APAP level should be measured 4 hr after the reported time of ingestion. For patients who present to medical care more than 4 hr after ingestion, a stat APAP level should be obtained. *APAP levels obtained <4 hr after ingestion, unless "nondetectable," are difficult to interpret and cannot be used to estimate the potential for toxicity.* Other important baseline labs include hepatic transaminases, renal function tests, and coagulation parameters.

Treatment. When considering the treatment of a patient poisoned or potentially poisoned with APAP, and after assessment of the ABCs, it is helpful to place the patient into one of the following 4 categories.

1. ***Prophylactic:*** By definition, these patients have a normal aspartate aminotransferase (AST). If the APAP level is known and the ingestion is within 24 hr of the level being drawn, then treatment

Table 63-10 Classic Stages in the Clinical Course of Acetaminophen Toxicity

STAGE	TIME AFTER INGESTION	CHARACTERISTICS
I	0.5-24 hr	Anorexia, vomiting, malaise Labs typically normal, except for acetaminophen level
II	24-48 hr	Resolution of earlier symptoms; right upper quadrant abdominal pain and tenderness; elevated hepatic transaminases (aspartate aminotransferase > alanine aminotransferase), INR
III	3-5 days	Peak transaminase elevations; development of liver failure, multi organ-system failure, death *or* recovery begins
IV	4 days-2 wk	Resolution of liver function abnormalities Clinical recovery precedes histologic recovery

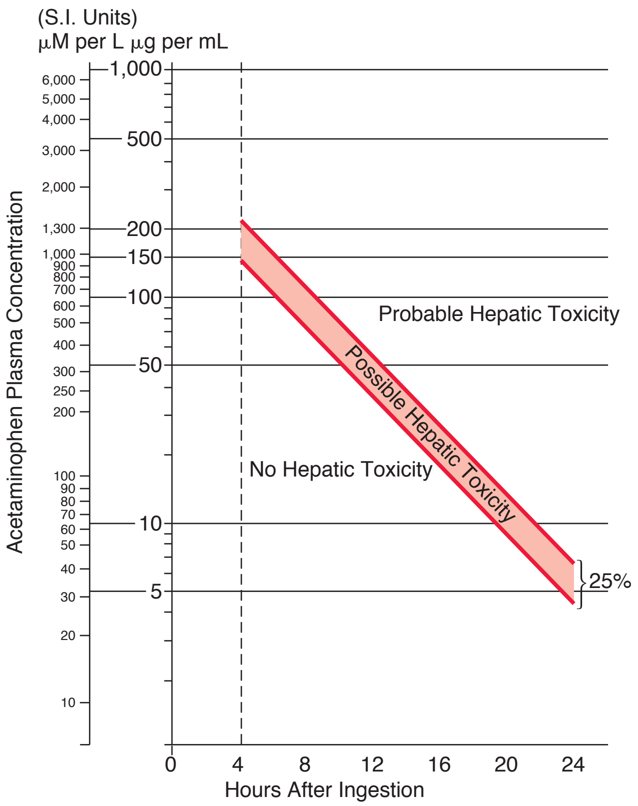

Figure 63-1 **Rumack-Matthew nomogram for acetaminophen poisoning, a semilogarithmic plot of plasma acetaminophen concentrations vs time.** Cautions for the use of this chart: The time coordinates refer to time after ingestion, serum concentrations obtained before 4 hr are not interpretable, and the graph should be used only in relation to a single acute ingestion with a known time of ingestion. This nomogram is not useful for chronic exposures or unknown time of ingestion and should be used with caution in the setting of coingestants that that slow gastrointestinal motility. The *lower solid line* is typically used in the United States to define toxicity and direct treatment, whereas the *upper line* is generally used in Europe. *(From Rumack BH, Hess AJ, editors:* Poisindex, *Denver, 1995, Micromedex. Adapted from Rumack BH, Matthew H: Acetaminophen poisoning and toxicity,* Pediatrics *55:871–876, 1975.)*

decisions are based on where the level falls on the Rumack-Matthew nomogram (Fig. 63-1). Any patient with a serum APAP level in the possible or probable hepatotoxicity range per the nomogram should be treated with *N*-acetylcysteine (NAC). This nomogram is only intended for use in patients who present within 24 hr of a single *acute* APAP ingestion with a known time of ingestion. If treatment is recommended, they should receive either oral Mucomyst or IV Acetadote for 24 or 21 hr, respectively. Repeat AST and APAP concentration drawn toward the end of that interval should be obtained. If the AST is normal and the APAP becomes nondetectable, then treatment may be discontinued. If the AST becomes elevated, then the patient moves into the next category of treatment (injury). If APAP is still present, treatment should be continued until the level is nondetectable. In the case of a patient with a documented APAP level, normal AST, and an unknown time of ingestion, treatment should ensue until the level is nondetectable, with normal transaminases.

The importance of instituting therapy with either IV or oral NAC no later than 8 hr from the time of ingestion cannot be overemphasized. No patient, no matter the size of the ingestion, who receives NAC within 8 hr of overdose should die from liver failure. The further out from the 8 hr mark the initiation of therapy is delayed, the greater the risk of acute liver failure. Any patient presenting close to that 8 hr mark or beyond it after an APAP overdose should be empirically started on NAC pending lab results.

2. ***Hepatic Injury:*** These patients are exhibiting evidence of hepatocellular necrosis, manifested first as elevated liver transaminases (AST rises first, then the alanine aminotransferase), followed by a rise in the INR. Any patient in this category requires therapy with NAC (IV or oral). When to discontinue therapy in the clinically well patient remains controversial, but in general, the transaminases and INR have peaked and fallen significantly "toward" normal (they do not need to be normal). Most patients' liver enzymes will peak 3 or 4 days after their ingestion.
3. ***Acute Liver Failure:*** The King's College criteria are used to determine which patients should be referred for consideration of liver transplant. These criteria include acidemia (serum pH <7.3) after adequate fluid resuscitation, coagulopathy (INR >6), renal dysfunction (creatinine >3.4 mg/dL), and grade III or IV hepatic encephalopathy (see Chapter 364). A serum lactic acid >3 mmol/L (after IV fluids) adds to both the sensitivity and specificity of the criteria to predict death without liver transplant. The degree of transaminase elevation does not factor in to this decision making process.
4. ***Repeated Supratherapeutic Ingestion:*** APAP is particularly prone to unintentional overdose through the ingestion of multiple medications containing the drug or simply because people assume it to be safe at any dose. Ingestion of amounts significantly greater than the recommended daily dose for several days or more puts one at risk for liver injury. Because the Rumack-Matthew nomogram is not helpful in this scenario, a conservative approach is in order. In the asymptomatic patient, if the AST is normal and the APAP is <10 μg/mL, then no therapy is indicated. A normal AST and an elevated APAP warrants NAC dosing for at least long enough for the drug to metabolize while the AST remains normal. An elevated AST puts the patient in the "hepatic injury" category described above. A patient presenting with symptoms (i.e., right upper quadrant pain, vomiting, jaundice) should be empirically started on NAC pending lab results.

NAC is available in oral and intravenous forms, and both are equally efficacious (see Table 63-7 for the dosing regimens of the oral vs IV form). The intravenous form is used in patients with intractable vomiting, those with evidence of hepatic failure, and pregnant patients. Oral NAC has an unpleasant taste and smell, and can be mixed in soft drink or fruit juice or given via nasogastric tube to improve tolerability of the oral regimen. Administration of IV NAC (as a standard 3% solution to avoid administering excess free water, typically in 5% dextrose), especially the initial loading dose, is associated in some patients with the development of anaphylactoid reactions (non–immunoglobulin E mediated). These reactions are typically managed by stopping the infusion; treating with diphenhydramine, albuterol, and/or epinephrine as indicated; and restarting the infusion at a slower rate once symptoms have resolved. IV NAC is also associated with mild elevation in measured INR (range: 1.2-1.5). IV dosing does, however, deliver less drug to the liver compared with the oral regimen. As a result, many toxicologists now recommend higher doses of the IV formulation in patients with large overdoses.

Transaminases, synthetic function, and renal function should be followed daily while the patient is being treated with NAC. Patients with worsening hepatic function or clinical status might benefit from more frequent lab monitoring. A patient-tailored approach is the norm for when to stop NAC therapy, for deciding whom to refer for transplantation evaluation, and often for the dose of IV NAC in patients with either very high APAP levels or signs of significant injury. Consultation with the regional poison center and medical toxicologist can help streamline the care of these patients, ultimately shortening their length of stay with potentially improved outcomes.

Salicylates. The incidence of salicylate poisoning in young children has declined dramatically since APAP and ibuprofen replaced aspirin as the most commonly used analgesics and antipyretics in

pediatrics. However, salicylates remain widely available, not only in aspirin-containing products but also in antidiarrheal medications, topical agents (e.g., keratolytics, sports creams), oil of wintergreen, and some herbal products. Oil of wintergreen contains 5 g of salicylate in 1 teaspoon (5 mL), meaning ingestion of very small volumes of this product has the potential to cause severe toxicity.

Pathophysiology. Salicylates lead to toxicity by interacting with a wide array of physiologic processes, including direct stimulation of the respiratory center, uncoupling of oxidative phosphorylation, inhibition of the tricarboxylic acid cycle, and stimulation of glycolysis and gluconeogenesis. The acute toxic dose of salicylates is generally considered to be >150 mg/kg. More significant toxicity is seen after ingestions of >300 mg/kg, and severe, potentially fatal, toxicity is described after ingestions of >500 mg/kg.

Clinical and Laboratory Manifestations. Salicylate ingestions are classified as acute or chronic, and acute toxicity is far more common in pediatric patients. Early signs of acute salicylism include nausea, vomiting, diaphoresis, and tinnitus. Moderate salicylate toxicity can manifest as tachypnea and hyperpnea, tachycardia, and altered mental status. The tachycardia results in large part from marked insensible losses from vomiting, tachypnea, diaphoresis, and uncoupling of oxidative phosphorylation. Thus, careful attention should be paid to volume status and early volume resuscitation in the significantly poisoned patient. Signs of severe salicylate toxicity include hyperthermia, coma, and seizures. Chronic salicylism can have a more insidious presentation, and patients can show marked toxicity at significantly lower salicylate levels than in acute toxicity.

Classically, lab values from a patient poisoned with salicylates reveal a primary respiratory alkalosis and a primary, elevated anion gap, metabolic acidosis. Early in the course of acute salicylism, respiratory alkalosis dominates. As the respiratory stimulation diminishes, the patient will move toward the metabolic acidosis. Hyperglycemia (early) and hypoglycemia (late) have been described. Abnormal coagulation studies and acute kidney injury may be seen but are not common.

Serial serum salicylate levels should be closely monitored (every 2-3 hr initially) until they are consistently down trending. Salicylate absorption in overdose is often unpredictable and erratic, especially with an enteric coated product, and levels can rapidly increase into the highly toxic range, even many hours after the ingestion. The Done nomogram is of poor value and should not be used. Serum and urine pH and electrolytes should be followed closely. An APAP level should be checked in any patient who intentionally overdoses on salicylates, because APAP is a common coingestant and because people often confuse or combine their nonprescription analgesic medications. Salicylate toxicity can cause a noncardiogenic pulmonary edema, especially in chronic overdose; consequently, a chest x-ray is recommended in any patient in respiratory distress.

Treatment. For the patient who presents soon after an acute ingestion, initial treatment should include gastric decontamination with activated charcoal. Salicylate pills occasionally form concretions called bezoars, which should be suspected if serum salicylate concentrations continue to rise many hours after ingestion or are persistently elevated in spite of appropriate management. Gastric decontamination is typically not useful after chronic exposure.

Initial therapy focuses on aggressive volume resuscitation and prompt initiation of sodium bicarbonate therapy in the symptomatic patient, even before obtaining serum salicylate levels. Therapeutic salicylate levels are 10-20 mg/dL, and levels >30 mg/dL warrant treatment.

The primary mode of therapy for salicylate toxicity is **urinary alkalinization**. Urinary alkalinization enhances the elimination of salicylates by converting salicylate to its ionized form, "trapping" it in the renal tubules, and thus enhancing elimination. In addition, maintaining an alkalemic serum pH decreases CNS penetration of salicylates because charged particles are less able to cross the blood–brain barrier. Alkalinization is achieved by administration of a sodium bicarbonate infusion at approximately 2 times maintenance fluid rates. *The goals of therapy include a urine pH of 7.5-8, a serum pH of 7.45-7.55, and decreasing serum salicylate levels.* In general, in the presence of an acidosis, an aspirin-poisoned patient's status can be directly related to the patient's serum pH. The lower the pH, the greater the relative amount of salicylate in the uncharged/nonpolar form and the greater the penetration of the blood–brain barrier by the drug. Careful attention should also be paid to serial potassium levels, because hypokalemia impairs alkalinization of the urine; potassium is often added to the bicarbonate drip. Repeat doses of charcoal may be beneficial because of the often delayed and erratic absorption of aspirin. Parenteral glucose should be provided to any salicylate poisoned patients with altered mental status as they may have CNS hypoglycemia not noted in a peripheral serum glucose test.

In cases of severe toxicity, hemodialysis may be required. Indications for dialysis include severe acid–base abnormalities (specifically severe acidosis and acidemia), a rising salicylate level despite adequate decontamination and properly alkalinized urine, pulmonary edema, cerebral edema, seizures, and renal failure. Serum salicylate concentrations should always be interpreted along with the clinical status of the patient; on their own they are not a clear indicator of the need for dialysis.

Ibuprofen and Other Nonsteroidal Antiinflammatory Drugs. Ibuprofen and other nonsteroidal antiinflammatory drugs (NSAIDs) are often involved in unintentional and intentional overdoses owing to their widespread availability and common use as analgesics and antipyretics. Fortunately, serious effects after NSAID overdose are rare owing to their wide therapeutic index.

Pathophysiology. NSAIDs inhibit prostaglandin synthesis by reversibly inhibiting the activity of cyclooxygenase (COX), the primary enzyme responsible for the biosynthesis of prostaglandins. In therapeutic use, side effects include GI irritation, reduced renal blood flow, and platelet dysfunction. In an attempt to minimize these side effects, NSAID analogs have been developed that are more specific for the inducible form of COX (the COX-2 isoform) than the constitutive form, COX-1. However, overdose of the more selective COX-2 inhibitors (e.g., celecoxib [Celebrex]) is treated the same as overdose of nonspecific COX inhibitors (e.g., ibuprofen) because at higher doses, COX-2–selective agents lose their COX inhibitory selectivity.

Ibuprofen, the primary NSAID used in pediatrics, is well tolerated, even in overdose. In children, acute doses of <200 mg/kg rarely cause toxicity, but ingestions of >400 mg/kg can produce more serious effects, including altered mental status and metabolic acidosis.

Clinical and Laboratory Manifestations. Symptoms usually develop within 4-6 hr of ingestion and resolve within 24 hr. If toxicity does develop, it is typically manifested as nausea, vomiting, and abdominal pain. Although GI bleeding and ulcers have been described with chronic use, they are rare in the setting of acute ingestion. After massive ingestions, patients can develop marked CNS depression, anion gap metabolic acidosis, renal insufficiency, and (rarely) respiratory depression. Seizures have also been described, especially after overdose of mefenamic acid. Specific drug levels are not readily available nor do they inform management decisions. Renal function studies, acid–base balance, complete blood count, and coagulation parameters should be monitored after very large ingestions. Coingestants, especially APAP, should be ruled out after any intentional ingestion.

Treatment. Supportive care, including use of antiemetics and acid blockade as indicated, is the primary therapy for NSAID toxicity. Decontamination with activated charcoal should be considered if a patient presents within 1-2 hr of a potentially toxic ingestion. There is no specific antidote for this class of drugs. Given the high degree of protein binding and excretion pattern of NSAIDs, none of the modalities used to enhance elimination are particularly useful in managing these overdoses. Unlike in patients with salicylate toxicity, urinary alkalinization is not helpful for NSAID toxicity. Patients who develop significant clinical signs of toxicity should be admitted to the hospital for ongoing supportive care and monitoring. Patients who remain asymptomatic for 4-6 hr after ingestion may be considered medically cleared.

Oral Opioids. Opioids are a commonly abused class of medications (see Chapter 114), both in their IV and oral forms. Two specific

oral opioids, buprenorphine and methadone, merit particular mention because of potential life-threatening toxicity in toddlers with ingestion of even 1 pill. Both agents are used in managing opioid dependence, although buprenorphine is the drug of choice. Methadone is also widely used in the treatment of chronic pain, meaning multiday prescriptions can be filled. Both drugs are readily available for illicit purchase and potential abuse. Both drugs are of great potential toxicity to a toddler, especially buprenorphine, owing to its long half-life and high potency.

Pathophysiology. Methadone is a lipophilic synthetic opioid with potent agonist effects at μ-opioid receptors, leading to both its desired analgesic effects and undesired side effects, including sedation, respiratory depression, and impaired GI motility. Methadone is thought to cause QTc interval prolongation via interactions with the human ether-a-go-go–related gene (hERG)-encoded potassium rectifier channel. Methadone has an average half-life of >25 hr, which may be extended to >50 hr in overdose.

Suboxone is a combination of buprenorphine, a potent opioid with partial agonism at μ-opioid receptors and weak antagonism at κ-opioid receptors, and naloxone. Naloxone has poor oral bioavailability but is included in the formulation to discourage diversion for intravenous use, during which it can precipitate withdrawal. Suboxone is formulated for buccal or sublingual administration; consequently, toddlers can absorb significant amounts of drug even by sucking on a tablet. Buprenorphine has an average half-life of 37 hr.

Clinical and Laboratory Manifestations. In children, methadone and buprenorphine ingestions can manifest with the classic opioid toxidrome of respiratory depression, sedation, and miosis. Signs of more-severe toxicity can include bradycardia, hypotension, and hypothermia. Even in therapeutic use, methadone is associated with a prolonged QTc interval and risk of torsades de pointes. Accordingly, an ECG should be part of the initial evaluation after ingestion of methadone or any unknown opioid. Neither drug is detected on routine urine opiate screens, although some centers have added a separate urine methadone screen. Levels of both drugs can be measured, although this is rarely done clinically and is seldom helpful in the acute setting. An exception may be in the cases involving concerns about neglect or abuse, at which point urine for gas chromatography/mass spectroscopy, the legal gold standard, should be sent to confirm and document the presence of the drug.

Treatment. Patients with significant respiratory depression or CNS depression should be treated with the opioid antidote, naloxone (see Table 63-7). In pediatric patients who are not chronically on opioids, the full reversal dose of 0.1 mg/kg (max: 2 mg/dose) should be used. In contrast, opioid-dependent patients should be treated with smaller initial doses (0.01 mg/kg), which can then be repeated as needed to achieve the desired clinical response, hopefully avoiding abrupt induction of withdrawal. Because the half-lives of methadone and buprenorphine are far longer than that of naloxone, patients can require multiple doses of naloxone. These patients may benefit from a continuous infusion of naloxone, typically started at two-thirds of the reversal dose/hr and titrated to maintain an adequate respiratory rate and level of consciousness. Patients who have ingested methadone should be placed on a cardiac monitor and have serial ECGs to monitor for the development of a prolonged QTc interval. If a patient does develop a prolonged QTc, management includes close cardiac monitoring, repletion of electrolytes (potassium, calcium, and magnesium), and having magnesium and a defibrillator readily available should the patient develop torsades de pointes.

Given the potential for clinically significant and prolonged toxicity, any toddler who has ingested methadone, even if asymptomatic, should be admitted to the hospital for at least 24 hr of monitoring. Some experts advocate a similar approach to management of buprenorphine ingestions, even in the asymptomatic patient. As we gain more experience with pediatric buprenorphine exposures, some patients who remain absolutely asymptomatic for 6-8 hr after ingestion and *have a stable social setting* may be candidates for earlier discharge. In the meantime, these cases should be discussed with a poison control center or medical toxicologist before determining disposition.

Cardiovascular Medications

β-Adrenergic Receptor Blockers. β Blockers competitively inhibit the action of catecholamines at the β receptor. Therapeutically, β blockers are used for a variety of conditions, including hypertension, coronary artery disease, tachydysrhythmias, anxiety disorders, migraines, essential tremor, and hyperthyroidism. Because of its lipophilicity and blockade of fast sodium channels, propranolol is considered to be the most toxic member of the β-blocker class. Overdoses of water-soluble β blockers (e.g., atenolol) are associated with milder symptoms.

Pathophysiology. In overdose, β blockers decrease chronotropy and inotropy in addition to slowing conduction through atrioventricular nodal tissue. Clinically, these effects are manifested as bradycardia, hypotension, and heart block. Patients with reactive airways disease can experience bronchospasm as a result of blockade of β_2-mediated bronchodilation. β_2 Blockers interfere with glycogenolysis and gluconeogenesis, which can sometimes lead to hypoglycemia, especially in patients with poor glycogen stores (e.g., toddlers).

Clinical and Laboratory Manifestations. Toxicity typically develops within 6 hr of ingestion, although it may be delayed after ingestion of sotalol or sustained-release preparations. The most common features of severe poisoning are bradycardia and hypotension. Lipophilic agents, including propranolol, can enter the CNS and cause altered mental status, coma, and seizures. Overdose of β blockers with membrane-stabilizing properties (e.g., propranolol) can cause QRS interval widening and ventricular dysrhythmias.

Evaluation after β-blocker overdose should include an ECG, frequent reassessments of hemodynamic status, and blood glucose. Serum levels of β blockers are not readily available for routine clinical use and are not useful in management of the poisoned patient.

Treatment. In addition to supportive care and GI decontamination as indicated, glucagon is the antidote of choice for β-blocker toxicity (see Table 63-7). Glucagon stimulates adenyl cyclase and increases levels of cyclic adenosine monophosphate independent of the β receptor. Glucagon is typically given as a bolus and, if this is effective, followed by a continuous infusion. In practice, however, glucagon is often only marginally effective, limited by its proemetic effects, especially at the doses typically required. Other potentially useful interventions include calcium, vasopressors, and high-dose insulin. Seizures are managed with benzodiazepines, and QRS widening should be treated with sodium bicarbonate. Children who ingest 1 or 2 water-soluble β blockers are unlikely to develop toxicity and can typically be discharged to home if they remain asymptomatic over a 6-hr observation period. Children who ingest sustained-release products, highly lipid-soluble agents, and sotalol can require longer periods of observation before safe discharge. Any symptomatic child should be admitted for ongoing monitoring and directed therapy.

Calcium Channel Blockers. Calcium channel blockers (CCBs) are used for a variety of therapeutic indications and have the potential to cause severe toxicity, even after exploratory ingestions. Specific agents include verapamil, diltiazem, and the dihydropyridines (e.g., amlodipine, nifedipine). Of these, diltiazem and verapamil are the most dangerous in overdose.

Pathophysiology. CCBs antagonize L-type calcium channels, inhibiting calcium influx into myocardial and vascular smooth muscle cells. Verapamil works primarily by slowing inotropy and chronotropy, and has no effect on systemic vascular resistance (SVR). Diltiazem has effects both on the heart and the peripheral vasculature. The dihydropyridines exclusively diminish SVR. Verapamil and diltiazem can significantly diminish myocardial contractility and conduction, with diltiazem also lowering SVR. By contrast, dihydropyridines will drop the SVR, leading to vasodilation and reflex tachycardia (though this receptor selectivity may be lost after a large overdose). Because the same L-type calcium channels blocked by CCBs are also on the pancreatic islet cells, it is the norm for any patient significantly poisoned with a CCB to be hyperglycemic.

Clinical and Laboratory Manifestations. The onset of symptoms typically is soon after ingestion, although it may be delayed with ingestions of sustained-release products. Overdoses of CCBs lead

to hypotension, accompanied by bradycardia, normal heart rate, or even tachycardia, depending on the agent. One unique characteristic of CCB overdose is that patients can exhibit profound hypotension with preserved consciousness.

Initial evaluation should include an ECG, continuous and careful hemodynamic monitoring, and rapid measurement of serum glucose levels. Both the absolute degree of hyperglycemia and the percentage increase in serum glucose have been correlated with the severity of CCB toxicity in adults. The development of hyperglycemia can even precede the development of hemodynamic instability. Blood levels of CCBs are not readily available and are not useful in guiding therapy.

Treatment. Once initial supportive care has been instituted, GI decontamination should begin with activated charcoal as appropriate. WBI may be beneficial in a stable patient after ingestion of a sustained-release product. Calcium channel blockade in the smooth muscles of the GI tract can lead to greatly diminished motility; thus, any form of GI decontamination should be undertaken with careful attention to serial abdominal exams.

Calcium salts, administered either through a peripheral IV as calcium gluconate, or via a central line as calcium chloride, help to overcome blocked calcium channels. *High-dose insulin euglycemia therapy is considered the antidote of choice for CCB toxicity.* An initial bolus of 1 unit/kg of regular insulin is followed by an infusion at 0.5-1 unit/kg/hr (see Table 63-6). The main mechanism of high-dose insulin euglycemia is to improve the metabolic efficiency of a poisoned heart that is in need of carbohydrates for energy (instead of the usual free fatty acids), but has minimal circulating insulin. Blood glucose levels should be closely monitored, and supplemental glucose may be given to maintain euglycemia, although this is rarely necessary in the severely poisoned patient. Additional therapies include judicious IV fluid boluses and vasopressors (often in very high doses). Cardiac pacing is rarely of value. Lipid emulsion therapy (discussed earlier), is a potentially life-saving intervention especially for patients poisoned with the more lipid soluble CCBs, verapamil and diltiazem. In extreme cases, an intraaortic balloon pump or extracorporeal membrane oxygenation are potential rescue devices. Given the potential for profound and sometimes delayed toxicity in toddlers after ingestion of 1 or 2 CCB tablets, hospital admission and 24 hr of monitoring for all of these patients is strongly recommended.

Clonidine. Although originally intended for use as an antihypertensive, clonidine prescriptions in the pediatric population have increased markedly, owing to its reported efficacy in the management of attention-deficit/hyperactivity disorder, tic disorders, and other behavioral disorders. With this increased use has come a significant increase in pediatric ingestions and therapeutic misadventures. Clonidine is available in pill and transdermal patch forms.

Pathophysiology. Clonidine, along with the closely related agent guanfacine, is a centrally acting α_2-agonist with a very narrow therapeutic index. Agonism at central α_2 receptors decreases sympathetic outflow, producing lethargy, bradycardia, hypotension, and apnea. Toxicity can develop after ingestion of as little as 1 pill or after sucking on or swallowing a discarded transdermal patch. Even a "used" transdermal patch might contain as much as one-third to one-half of the original amount of drug.

Clinical and Laboratory Manifestations. The most common clinical manifestations of clonidine toxicity include lethargy, miosis, and bradycardia. Hypotension, respiratory depression, and apnea may be seen in severe cases. Very early after ingestion, patients may be hypertensive in the setting of agonism at peripheral α receptors and resulting vasoconstriction. Symptoms develop relatively soon after ingestion and typically resolve within 24 hr. Serum clonidine concentrations are not readily available and are of no clinical value in the acute setting. Though signs of clinical toxicity are common after clonidine overdose, death from clonidine alone is extremely unusual.

Treatment. Given the potential for significant toxicity, most young children warrant referral to a healthcare facility for evaluation after unintentional ingestions of clonidine. Gastric decontamination is usually of little value, owing to the small quantities ingested and the rapid onset of serious symptoms. Aggressive supportive care is imperative and is the cornerstone of management. Naloxone, often in high doses, has shown variable efficacy in treating clonidine toxicity. Other potentially useful therapies include atropine, IV fluid boluses, and vasopressors. Symptomatic children should be admitted to the hospital for close cardiovascular and neurologic monitoring. It should also be noted, that in a patient chronically on clonidine or guanfacine, rapid discontinuation of the drug, or even missing 1 or 2 doses, could lead to potentially dangerous elevations in blood pressure.

Digoxin. Digoxin is a cardiac glycoside extracted from the leaves of *Digitalis lanata*. Other natural sources of cardiac glycosides include *Digitalis purpura* (foxglove), *Nerium oleander* (oleander), *Convallaria majalis* (lily of the valley), Siberian ginseng, and the *Bufo marinus* toad. Therapeutically, digoxin is used in the management of heart failure and some supraventricular tachydysrhythmias. Acute overdose can occur in the setting of dosing errors (especially in younger children), unintentional or intentional medication ingestion, or exposure to plant material containing digitalis glycosides. Regarding exposure to such plants, toxicity is unusual unless the poison is concentrated in the form of a tea. Chronic toxicity can result from alteration of the digoxin dose, alteration in digoxin clearance as a result of renal impairment, or drug interactions.

Pathophysiology. Digoxin blocks the Na^+, K^+-ATPase (adenosine triphosphatase) pump, leading to intracellular loss of K^+ and gain of Na^+ and Ca^{2+}. This resulting rise in Ca^{2+} available to the contractile myocardium improves inotropy. An increase in myocardial automaticity leads to subsequent atrial, nodal, and ventricular ectopy. Digoxin also affects nodal conduction, leading to a prolonged refractory period, decreased sinus node firing, and slowed conduction through the atrioventricular node. Impaired Na-K exchange results in dangerously high levels of serum potassium. Overall, digoxin overdose manifests as a combination of slowed or blocked conduction and increased ectopy.

Clinical and Laboratory Manifestations. Nausea and vomiting are common initial symptoms of acute digoxin toxicity, manifesting within 6 hr of overdose. Cardiovascular manifestations include bradycardia, heart block, and a wide variety of dysrhythmias. CNS manifestations consist of lethargy, confusion, and weakness. Chronic toxicity is more insidious and manifests with GI symptoms, altered mental status, and visual disturbances.

Initial assessment should include an ECG, serum digoxin level, serum potassium, and kidney function tests. The serum digoxin level should be assessed at least 6 hr after ingestion and carefully interpreted in the setting of clinical symptoms because the digoxin level alone does not entirely reflect the severity of intoxication. In acute ingestions, serum potassium is an independent marker of morbidity and mortality, with levels >5.5 mEq/L predicting poor outcomes. In chronic toxicity, serum potassium is less useful as a prognostic marker and may be altered due to concomitant use of diuretics.

Digoxin has a very narrow therapeutic index. Therapeutic plasma digoxin concentrations are 0.5-2.0 ng/mL; a level >2 ng/mL is considered toxic and a level >6 ng/mL is considered potentially fatal (in chronic poisonings). Numerous drug interactions affect plasma digoxin concentrations. Medications known to increase serum digoxin concentrations include the macrolides, erythromycin and clarithromycin, spironolactone, verapamil, amiodarone, and itraconazole.

Treatment. Initial treatment includes good general supportive care and gastric decontamination with activated charcoal if the ingestion was recent. An antidote for digoxin, digoxin-specific Fab antibody fragments (Digibind or DigiFab) is available (see Table 63-7). Fab fragments bind free digoxin in both the intravascular and the interstitial spaces to form a pharmacologically inactive complex that is subsequently renally eliminated. Indications for Fab fragments include life-threatening dysrhythmias, K^+ value >5-5.5 mEq/L, serum digoxin level >15 ng/mL at any time or >10 ng/mL 6 hr after ingestion, ingestion >4 mg in children or >10 mg in adults, clinically significant hypotension or other cardiovascular instability, altered mental status, and renal failure. Atropine is potentially useful in managing symptomatic bradycardia. Although dogma states that patients on digoxin with severe hyperkalemia and QRS widening on the ECG should not receive calcium salts, this has not been supported in the literature. Once

stabilized, consultation with a cardiologist is recommended in the management of patients chronically on digoxin, because administration of Fab fragments can lead to recurrence of the patient's underlying dysrhythmias or dysfunction.

Iron. Historically, iron was a common cause of childhood poisoning deaths. However, preventive measures such as childproof packaging have significantly decreased the rates of serious iron toxicity in young children. Iron-containing products remain widely available, with the most potentially toxic being adult iron preparations and prenatal vitamins. The severity of an exposure is related to the amount of *elemental iron* ingested. Ferrous sulfate contains 20% elemental iron, ferrous gluconate 12%, and ferrous fumarate 33%. Multivitamin preparations and children's vitamins rarely contain enough elemental iron to cause significant toxicity.

Pathophysiology. Iron is directly corrosive to the GI mucosa, leading to hematemesis, melena, ulceration, infarction, and potential perforation. Early iron-induced hypotension is caused by massive volume losses, increased permeability of capillary membranes, and venodilation mediated by free iron. Iron accumulates in tissues, including the Kupffer cells of the liver and myocardial cells, leading to hepatotoxicity, coagulopathy, and cardiac dysfunction. Metabolic acidosis develops in the setting of hypotension, hypovolemia, and iron's direct interference with oxidative phosphorylation and the Krebs cycle. Pediatric patients who ingest >40 mg/kg of elemental iron should be referred to medical care for evaluation, although moderate to severe toxicity is typically seen with ingestions of >60 mg/kg.

Clinical and Laboratory Manifestations. Iron toxicity is classically described in 4, often overlapping, stages. The initial stage, 30 min to 6 hr after ingestion, consists of profuse vomiting and diarrhea (often bloody), abdominal pain, and significant volume losses leading to potential hypovolemic shock. Patients who do not develop GI symptoms within 6 hr of ingestion are unlikely to develop serious toxicity. The 2nd stage, 6-24 hr after ingestion, is often referred to as the "quiescent phase," as GI symptoms typically have resolved. However, careful clinical exam can reveal subtle signs of hypoperfusion, including tachycardia, pallor, and fatigue. During the 3rd stage, occurring 12-36 hr after ingestion, patients develop multisystem organ failure, shock, hepatic and cardiac dysfunction, acute lung injury or acute respiratory distress syndrome (ARDS), and profound metabolic acidosis. Death occurs most commonly during this stage. In patients who survive, the 4th stage (4-6 wk after ingestion) is marked by formation of strictures and signs of GI obstruction.

Symptomatic patients and patients with a large exposure by history should have serum iron levels drawn 4-6 hr after ingestion. Serum iron concentrations of <500 µg/dL 4-8 hr after ingestion suggest a low risk of significant toxicity, whereas concentrations of >500 µg/dL indicate that significant toxicity is likely. Additional lab evaluation in the ill patient should include arterial blood gas, complete blood count, serum glucose level, liver function tests, and coagulation parameters. Careful attention should be paid to ongoing monitoring of the patient's hemodynamic status. An abdominal x-ray might reveal the presence of iron tablets, though not all formulations of iron are radiopaque.

Treatment. Close clinical monitoring, combined with aggressive supportive and symptomatic care, is essential to the management of iron poisoning. Activated charcoal does not adsorb iron, and WBI remains the decontamination strategy of choice. Deferoxamine, a specific chelator of iron, is the antidote for moderate to severe iron intoxication (see Table 63-7). Indications for deferoxamine treatment include a serum iron concentration of >500 µg/dL or moderate to severe symptoms of toxicity, regardless of serum iron concentration. Deferoxamine is preferably given via continuous IV infusion at a rate of 15 mg/kg/hr. Hypotension is a common side effect of deferoxamine infusion and is managed by slowing the rate of the infusion and administering fluids and/or vasopressors as needed. Prolonged deferoxamine infusion (>24 hr) has been associated with pulmonary toxicity (ARDS) and *Yersinia* sepsis. The deferoxamine–iron complex can color the urine reddish ("vin rosé"), although this is an unreliable indicator of iron excretion. Clear end points for deferoxamine chelation are not well defined, but therapy is typically continued until clinical symptoms resolve. Consultation with a poison control center or medical toxicologist can yield guidelines for discontinuing deferoxamine.

Oral Hypoglycemics

Oral medications used in the management of type 2 diabetes include sulfonylureas, biguanides (e.g., metformin), thiazolidinediones, and meglitinides. Of these, only the sulfonylureas and meglitinides have the potential to cause profound hypoglycemia in both diabetic and nondiabetic patients. These classes of medications are widely prescribed and thus readily available for both unintentional and intentional exposures. In toddlers, ingestion of a single sulfonylurea tablet can lead to significant toxicity.

Pathophysiology. Sulfonylureas work primarily by enhancing endogenous insulin secretion. In binding to the sulfonylurea receptor, these drugs induce closure of potassium channels, leading to membrane depolarization, opening of calcium channels, and stimulation of calcium-mediated insulin release. Even in therapeutic use, the duration of hypoglycemic action can last up to 24 hr.

Clinical and Laboratory Manifestations. Hypoglycemia and symptoms associated with hypoglycemia are the primary clinical manifestations of sulfonylurea toxicity. These signs and symptoms can include diaphoresis, tachycardia, lethargy, irritability, coma, seizures, and even focal neurologic findings. As with other hyperinsulinemic states, sulfonylurea overdoses are associated with a nonketotic hypoglycemia. In the majority of cases, hypoglycemia develops within 6 hr of ingestion but can be delayed up to 16-18 hr after ingestion. Toddlers are particularly susceptible to hypoglycemia during an overnight fast.

Treatment. Patients with symptomatic hypoglycemia should be promptly treated with dextrose. In patients with mild symptoms, oral dextrose may be sufficient. However, patients with severe symptoms or profound hypoglycemia should be treated with a bolus of IV dextrose. Continuous dextrose infusions and repeated IV dextrose boluses should be avoided if possible, because this can stimulate further insulin release and lead to recurrent and prolonged hypoglycemia. Instead, the preferred antidote for symptomatic sulfonylurea toxicity is octreotide (see Table 63-7). Octreotide is a somatostatin analog that works via inhibiting insulin release. Octreotide is given IV or SC, typically in doses of 1-2 µg/kg (50-100 µg in adults) every 6-8 hr.

Given the potential for significant hypoglycemia, toddlers with witnessed or suspected sulfonylurea ingestions should be admitted to the hospital for monitoring and serial glucose measurements, at least for 12 hr, including an overnight fast. Patients of any age who develop hypoglycemia are also candidates for admission given the prolonged duration of hypoglycemic activity. Prophylactic IV dextrose infusions are not recommended because they can mask the symptoms of toxicity and stimulate further insulin secretion. Patients who require IV dextrose and/or octreotide should be monitored until they can demonstrate euglycemia for at least 8 hr off of all therapy.

With the increasing numbers of adolescents with type 2 diabetes, pediatricians should be familiar with the toxic effects of metformin as well. Although this agent does not cause hypoglycemia, its association with lactic acidosis is well documented (Metformin Associated Lactic Acidosis–MALA). This state typically arises after a large overdose in which the agent interferes with the liver's ability to clear lactic acid. Dangerously high serum lactate levels can result, leading to hemodynamic instability. Hemodialysis is usually the best option for patients with severe metformin-associated lactic acidosis.

Psychiatric Medications: Antidepressants

Selective serotonin reuptake inhibitors (SSRIs; e.g., fluoxetine, sertraline, paroxetine, citalopram) are the most commonly prescribed class of antidepressants. This trend results in large part from their wide therapeutic index and more favorable side-effect profile when compared to older agents such as tricyclic antidepressants (TCAs; amitriptyline, clomipramine, desipramine, doxepin, nortriptyline, imipramine) and monoamine oxidase inhibitors. Newer agents include the serotonin and norepinephrine reuptake inhibitors (e.g., venlafaxine) and other atypical antidepressants (e.g., bupropion).

Tricyclic Antidepressants. Although TCAs are now prescribed less commonly for depression, they remain in use for a variety of other conditions, including chronic pain syndromes, enuresis, attention-deficit/hyperactivity disorder, and obsessive compulsive disorder. TCAs can cause significant toxicity in children, even with ingestion of 1 or 2 pills (10-20 mg/kg).

Pathophysiology. TCAs achieve their desired antidepressant effects primarily via blockade of norepinephrine and serotonin reuptake. TCAs have complex interactions with other receptor types. Antagonism at muscarinic acetylcholine receptors leads to clinical features of the anticholinergic toxidrome. Antagonism at peripheral α-receptors leads to hypotension and syncope. Key to the toxicity of TCAs is their ability to block fast sodium channels, leading to impaired cardiac conduction and arrhythmias.

Clinical and Laboratory Manifestations. Cardiovascular and CNS symptoms dominate the clinical presentation of TCA toxicity. Symptoms typically develop within 1-2 hr of ingestion, and serious toxicity usually manifests within 6 hr of ingestion. Patients can have an extremely rapid progression from mild symptoms to life-threatening dysrhythmias. Patients often develop features of the anticholinergic toxidrome, including delirium, mydriasis, dry mucous membranes, tachycardia, hyperthermia, urinary retention, and slow GI motility. CNS toxicity can include lethargy, coma, myoclonic jerks, and seizures. Sinus tachycardia is the most common cardiovascular manifestation of toxicity; however, patients can develop widening of the QRS complex, premature ventricular contractions, and ventricular arrhythmias. Refractory hypotension is a poor prognostic indicator and is the most common cause of death in TCA overdose.

An ECG is a readily available bedside test that can help determine the diagnosis and prognosis of the TCA-poisoned patient (Fig. 63-2). A QRS duration of >100 msec identifies patients who are at risk for seizures and cardiac arrhythmias. An R wave in lead aVR of ≥3 mm is also an independent predictor of toxicity. Both of these ECG parameters are superior to measured serum TCA concentrations in identifying patients at risk for serious toxicity, and obtaining levels is rarely helpful in management of the acutely ill patient.

Treatment. Initial attention should be directed to supporting vital functions, including airway and ventilation support as needed. Gastric decontamination can be accomplished with activated charcoal in appropriate patients. Treating clinicians should obtain an ECG as soon as possible and follow serial ECGs to monitor for progression of toxicity.

Four primary effects seen at the bedside, along with their treatment recommendations, are listed here:

1. ***Altered mental status:*** TCA-poisoned patients can become deeply comatose relatively quickly, so careful and prompt attention to the airway and placement of an endotracheal tube is of paramount importance. The airway should be secured prior to any GI decontamination efforts.
2. ***Widened QRS on the ECG:*** TCAs (along with other agents such as diphenhydramine, cocaine, etc) will block the fast sodium channels on the myocardial cells, slowing the upstroke of the QRS complex. Because the effect on sodium channels is greatest within the 1st 6 hr, frequent ECGs (i.e., every 20-30 min) during this time frame are important. As the QRS approaches 160 msec, the chance of the patient developing monomorphic ventricular tachycardia rises to 30%. Sodium, usually in the form of sodium bicarbonate, is the antidote of choice. *Indications for sodium bicarbonate include a QRS duration ≥110 msec, ventricular dysrhythmias, and hypotension.* Multiple bolus doses of sodium bicarbonate, 1-2 mEq/kg each, may be needed to narrow the QRS to <110 msec. Some authors prefer to then place the patient on an infusion of sodium bicarbonate, but this may not be necessary if careful attention is paid to the QRS after the initial doses and repeat bolus dosing is provided as needed during those 1st 6-12 hr. Hypertonic (3%) saline and/or lipid emulsion therapy may be beneficial in refractory cases.
3. ***Hypotension:*** A direct acting vasopressor, such as norepinephrine or epinephrine, is the agent of choice. Boluses of intravenous crystalloid fluids should be used with caution to prevent fluid overload.
4. ***Seizures:*** Likely a result of the anticholinergic effects of TCAs, seizures are relatively common, typically brief, and should be treated with agents the work on the γ-aminobutyric acid receptor complex in the brain. Benzodiazepines are the agent of choice.

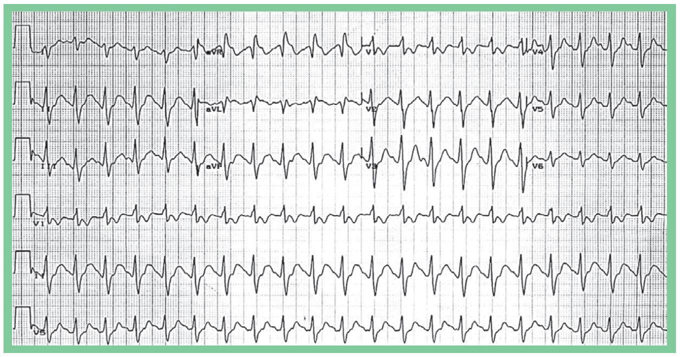

Figure 63-2 Electrocardiographic findings in tricyclic antidepressant toxicity. Note the tachycardia, widened QRS interval (144 msec), and prominent R wave in lead aVR. These findings are consistent with blockade of fast sodium channels.

Asymptomatic children should receive appropriate decontamination and be observed with continuous cardiac monitoring and serial ECGs for at least 6 hr. If any manifestations of toxicity develop, the child should be admitted to a monitored setting. Children who remain completely asymptomatic with normal serial ECGs may be candidates for discharge after 6 hr of close observation.

Selective Serotonin Reuptake Inhibitors. In overdose, SSRIs are considerably less toxic than TCAs. SSRIs are unlikely to cause significant toxicity in exploratory ingestions. Some data suggest that initiating SSRI therapy is associated with an increased risk of suicidal ideation and behavior (see Chapter 21).

Pathophysiology. SSRIs selectively block the reuptake of serotonin in the CNS. In contrast to TCAs and atypical antidepressants, SSRIs do not directly interact with other receptor types.

Clinical and Laboratory Manifestations. In overdose, the principal manifestations of toxicity are sedation and tachycardia. Cardiac conduction abnormalities (primarily QTc prolongation) and seizures have been described in significant overdoses, especially after ingestions of citalopram. An ECG should be part of the initial assessment after SSRI ingestion. Serum creatine kinase levels are almost always elevated in a patient with clinically significant serotonin syndrome.

Although development of the **serotonin syndrome** is seen more often after therapeutic use or overdose of several serotonergic agents in combination, it has also been described in ingestions of SSRIs alone (Table 63-11). Clinically, serotonin syndrome describes a spectrum of altered mental status, autonomic instability, fever, and neuromuscular hyperactivity (hyperreflexia, tremors, clonus in the lower extremities more than the upper extremities). One or all of these signs may be present to varying degrees.

Treatment. Initial management includes a careful assessment for signs and symptoms of serotonin syndrome and an ECG. Most patients simply require supportive care and observation until their mental status improves and tachycardia, if present, resolves. Management of serotonin syndrome is directed by the severity of symptoms; possible therapeutic interventions include benzodiazepines in mild cases and intubation, sedation, and paralysis in patients with severe manifestations (e.g., significant hyperthermia). Because agonism at the 5-HT_{2A} serotonin receptor is thought to be primarily responsible for the development of serotonin syndrome, use of the $5HT_{2A}$ receptor antagonist cyproheptadine is also beneficial. Cyproheptadine is only available in an oral form.

Atypical Antidepressants. The class known as atypical antidepressants includes agents such as venlafaxine and duloxetine (serotonin and norepinephrine reuptake inhibitors), bupropion (dopamine, norepinephrine, and some serotonin reuptake blockade), and

Table 63-11 Drugs Associated with the Serotonin Syndrome

DRUG TYPE	DRUGS
Selective serotonin reuptake inhibitors	Sertraline, fluoxetine, fluvoxamine, paroxetine, citalopram
Antidepressant drugs	Trazodone, nefazodone, buspirone, clomipramine, venlafaxine
Monoamine oxidase inhibitors	Phenelzine, moclobemide, clorgyline, isocarboxazid
Anticonvulsants	Valproate
Analgesics	Meperidine, fentanyl, tramadol, pentazocine
Antiemetic agents	Ondansetron, granisetron, metoclopramide
Antimigraine drugs	Sumatriptan
Bariatric medications	Sibutramine
Antibiotics	Linezolid (a monoamine oxidase inhibitor), ritonavir (through inhibition of cytochrome P450 enzyme isoform 3A4)
Nonprescription cough and cold remedies	Dextromethorphan
Drugs of abuse	Methylenedioxymethamphetamine (MDMA, or "ecstasy"), lysergic acid diethylamide (LSD), 5-methoxydiisopropyltryptamine ("foxy methoxy"), Syrian rue (contains harmine and harmaline, both monoamine oxidase inhibitors)
Dietary supplements and herbal products	Tryptophan, *Hypericum perforatum* (St. John's wort), *Panax ginseng* (ginseng)
Other	Lithium

From Boyer EW, Shannon M: The serotonin syndrome, N Engl J Med *352:1112–1120, 2005.*

trazodone (serotonin reuptake blockade and peripheral α-receptor antagonism). The variable receptor affinities of these agents lead to some distinctions in their clinical manifestations and management.

Clinical and Laboratory Manifestations. In overdose, venlafaxine and other serotonin and norepinephrine reuptake inhibitors are associated with cardiac conduction defects, including QRS and QTc prolongation, and seizures. Bupropion is one of the most common etiologies of toxicant-induced seizures in the United States. After ingestion of sustained or extended-release preparations, seizures can occur as late as 18-20 hr after ingestion. In addition, bupropion can cause tachycardia, agitation, and QRS and QTc prolongation. The structure of bupropion contains an amphetamine moiety, which can cause a false-positive result on the urine amphetamine screen. In addition to sedation and signs of serotonin excess, trazodone overdose may be associated with hypotension from blockade of peripheral α-receptors.

Treatment. Management is directed to clinical signs and symptoms. QRS interval prolongation may be treated with IV sodium bicarbonate as described in detail earlier. Seizures are often brief and self-limited, but they can be treated with benzodiazepines if necessary. Trazodone-associated hypotension typically responds to fluids, though it can require vasopressors in extreme cases. Because of the potential for delayed seizures, patients who ingest a sustained-release preparation of bupropion should be admitted to a monitored setting for at least 20-24 hr of observation.

Monoamine Oxidase Inhibitors. Monoamine oxidase inhibitors are now rarely used therapeutically; however, they remain important agents to know about given their potential for serious and delayed toxicity. Ingestions of as little as 1 or 2 pills (6 mg/kg) are associated with toxicity in children. Clinical manifestations initially include hypertension, hyperthermia, tachycardia, muscle rigidity, and seizures followed up to 24 hr later by hemodynamic instability and cardiovascular collapse. *Any child who ingests a monoamine oxidase inhibitor should be admitted to a monitored setting for at least 24 hr, regardless of symptoms.* Management includes blood pressure control, cooling and benzodiazepines for hyperthermia, serial monitoring of creatine kinase and renal function, and fluid and vasopressor therapy for hemodynamic instability.

Psychiatric Medications: Antipsychotics

Clinicians are increasingly prescribing antipsychotic medications in the pediatric population. Antipsychotic medications are commonly classified as either typical or atypical. In general, typical agents are associated with more side effects and toxicity than the atypical agents.

Pathophysiology. Typical or traditional antipsychotics (i.e., haloperidol, droperidol, thioridazine, chlorpromazine, and fluphenazine) are characterized by their antagonism at D_2 dopamine receptors. In therapeutic use, these agents are associated with extrapyramidal symptoms, tardive dyskinesia, and development of the neuroleptic malignant syndrome (NMS). The atypical agents (i.e., aripiprazole, clozapine, quetiapine, risperidone, ziprasidone) were developed with less dopamine (D_2-receptor) antagonism in efforts to avoid these side effects and improve their efficacy in managing the "negative" symptoms of schizophrenia. Instead, these agents have complex and varied interactions with multiple receptor types, including α-receptors, serotonin receptors, muscarinic acetylcholine receptors, and histamine receptors.

Clinical and Laboratory Manifestations. Typical antipsychotic toxicity commonly includes sedation, tachycardia, and prolongation of the QTc interval. Patients can present with acute dystonia, akathisia, and NMS, although these are seen less commonly in acute overdoses than in therapeutic use. The phenothiazines (e.g., thioridazine) can cause widening of the QRS interval owing to blockade of fast sodium channels. Clinically, NMS can be difficult to distinguish from serotonin syndrome.

Although the presentation of atypical antipsychotic toxicity can vary based on the receptor affinities of the specific agent, sedation, tachycardia, and QTc prolongation are common. Peripheral α-receptor blockade (e.g., with quetiapine) is associated with hypotension. In therapeutic use, clozapine is associated with agranulocytosis.

Diagnostic testing should include an ECG. Patients with hyperthermia or muscle rigidity should have a serum creatine kinase level sent to monitor for possible rhabdomyolysis. Antipsychotic levels are not readily available and are not helpful in managing acute poisoning.

Management. Initial management involves assessing and supporting vital functions. In some patients, CNS depression may be so profound as to require intubation for airway control. Acute dystonia is treated with diphenhydramine, benztropine, and sometimes benzodiazepines. Management of NMS includes conscientious supportive care, IV fluids, cooling, benzodiazepines, and bromocriptine or dantrolene in severe cases. QTc prolongation is managed with repletion of electrolytes (especially calcium, magnesium, and potassium), continuous cardiac monitoring, overdrive pacing, IV magnesium sulfate and/or defibrillation if the patient develops torsades de pointes. Seizures typically are well controlled with benzodiazepines. Hypotension usually responds to boluses of IV fluids, though vasopressor therapy is necessary in some cases.

Household Products

Caustics

Caustics include acids and alkalis as well as a few common oxidizing agents (see Chapter 327). Strong acids and alkalis can produce severe injury even in small-volume ingestions.

Pathophysiology. Alkalis produce a liquefaction necrosis, allowing further tissue penetration of the toxin and setting the stage for possible perforation. Acids produce a coagulative necrosis, which limits further tissue penetration, though perforation can still occur. The severity of the corrosive injury depends on the pH and

concentration of the product as well as the length of contact time with the product. Agents with a pH of <2 or >12 are most likely to produce significant injury.

Clinical Manifestations. Ingestion of caustic materials can produce injury to the oral mucosa, esophagus, and stomach. Patients can have significant esophageal injury even in the absence of visible oral burns. Symptoms include pain, drooling, vomiting, abdominal pain, and difficulty swallowing or refusal to swallow. Laryngeal injury can manifest as stridor and respiratory distress, necessitating intubation. In the most severe cases, patients can present in shock after perforation of a hollow viscus. Circumferential burns of the esophagus are likely to cause strictures when they heal, which can require repeated dilation or surgical correction and long-term follow-up for neoplastic changes in adulthood (see Chapter 327.2). Caustics on the skin or in the eye can cause significant tissue damage.

Treatment. Initial treatment of caustic exposures includes thorough removal of the product from the skin or eye by flushing with water. Emesis and lavage are contraindicated. Activated charcoal should not be used because it does not bind these agents and can predispose the patient to vomiting and subsequent aspiration. Stridor or other signs of respiratory distress should alert the provider to the need for a thorough evaluation of the airway for potential intubation or surgical airway management. Endoscopy can be performed within 12-24 hr of ingestion for prognostic and diagnostic purposes in symptomatic patients or those in whom injury is suspected on the basis of history and known characteristics of the ingested product. Endoscopy is contraindicated in any patient with signs of peritonitis. The use of corticosteroids or prophylactic antibiotics is not beneficial.

Cholinesterase-Inhibiting Insecticides

The most commonly used insecticides are organophosphates and carbamates; both are inhibitors of cholinesterase enzymes (acetylcholinesterase, pseudocholinesterase, and erythrocyte acetylcholinesterase). Most pediatric poisonings occur as the result of unintentional exposure to insecticides in and around the home or farm. The class of chemical warfare weapons known as "nerve agents" are also organophosphate compounds with a similar mechanism of action, but much greater potency.

Pathophysiology. Organophosphates and carbamates produce toxicity by binding to and inhibiting acetylcholinesterase, preventing the degradation of acetylcholine and resulting in its accumulation at nerve synapses. If left untreated, organophosphates form an irreversible bond to acetylcholinesterase, permanently inactivating the enzyme. This process, called *aging*, occurs over a variable time period depending on the characteristics of the specific organophosphate. Afterwards, a period of weeks to months is required to regenerate inactivated enzymes. In contrast, carbamates form a temporary bond to the enzymes, typically allowing reactivation of acetylcholinesterase within 24 hr.

Clinical and Laboratory Manifestations. Clinical manifestations of organophosphate and carbamate toxicity relate to the accumulation of acetylcholine at peripheral nicotinic and muscarinic synapses and in the CNS. Symptoms of carbamate toxicity are usually less severe than those seen with organophosphates. A commonly used mnemonic for the symptoms of cholinergic excess at muscarinic receptors is ***DUMBBELS***, which stands for *d*iarrhea/defecation, *u*rination, *m*iosis, *b*ronchorrhea/*b*ronchospasm, *b*radycardia, *e*mesis, *l*acrimation, and *s*alivation. Nicotinic signs and symptoms include muscle weakness, fasciculation, tremors, hypoventilation (diaphragm weakness), hypertension, tachycardia, and dysrhythmias. Severe manifestations include coma, seizures, shock, arrhythmias, and respiratory failure.

Diagnosis of poisoning is based primarily on history and physical exam findings. Red blood cell cholinesterase and pseudocholinesterase activity levels can be measured in the laboratory. These are only helpful when compared to the patient's known baseline. As such, these assessments are typically limited to farm workers undergoing ongoing occupational surveillance.

Treatment. Basic decontamination should be performed, including washing all exposed skin with soap and water and immediately removing all exposed clothing. Activated charcoal is unlikely to be of benefit as these are liquids that are rapidly absorbed. Basic supportive care should be provided, including fluid and electrolyte replacement and intubation and ventilation if necessary. The use of succinylcholine for rapid sequence intubation should be avoided as this paralytic is metabolized by the same cholinesterase enzymes now poisoned, leading to prolonged paralysis.

Two antidotes are useful in treating cholinesterase inhibitor poisoning: atropine and pralidoxime (see Table 63-7). Atropine, which antagonizes the muscarinic acetylcholine receptor, is useful for both organophosphate and carbamate intoxication. Often, large doses of atropine must be administered by intermittent bolus or via continuous infusion to control symptoms. Atropine dosing is primarily targeted to drying the respiratory secretions. Pralidoxime breaks the bond between the organophosphate and the enzyme, reactivating acetylcholinesterase. Pralidoxime is only effective if it is used before the bond ages and becomes permanent. Pralidoxime is not necessary for carbamate poisonings because the bond between the insecticide and the enzyme degrades spontaneously.

Without treatment, symptoms of organophosphate poisoning can persist for weeks, requiring continuous supportive care. Even with treatment, some patients develop a delayed polyneuropathy and a range of chronic neuropsychiatric symptoms.

Hydrocarbons

Hydrocarbons include a wide array of chemical substances found in thousands of commercial products. Specific characteristics of each product determine whether exposure will produce systemic toxicity, local toxicity, both, or neither. Nevertheless, aspiration of even small amounts of certain hydrocarbons can lead to serious, potentially life-threatening toxicity.

Pathophysiology. The most important manifestation of hydrocarbon toxicity is aspiration pneumonitis via inactivation of the type II pneumocytes and resulting surfactant deficiency (see Chapter 397). Aspiration usually occurs during coughing and gagging at the time of ingestion or vomiting after the attempted ingestion of an aliphatic hydrocarbon. The propensity of a hydrocarbon to cause aspiration pneumonitis is inversely proportional to its viscosity, and directly proportional to its volatility. Compounds with low viscosity and high volatility, such as mineral spirits, naphtha, kerosene, gasoline, and lamp oil, spread rapidly across surfaces and cover large areas of the lungs when aspirated. Only small quantities (<1 mL) of such chemicals need be aspirated to produce significant injury. Pneumonitis does not result from dermal absorption of hydrocarbons or from ingestion in the absence of aspiration. Gasoline and kerosene are poorly absorbed, but they often cause considerable irritation of the GI mucosa as they pass through the intestines.

Certain hydrocarbons have unique toxicities and can cause symptoms after ingestion, inhalation, or dermal exposures. Several chlorinated solvents, most notably carbon tetrachloride, can produce hepatic toxicity. Methylene chloride, found in some paint removers, is metabolized to carbon monoxide. Benzene is known to cause cancer, most commonly acute myelogenous leukemia, after long-term exposure. Nitrobenzene, aniline, and related compounds can produce methemoglobinemia. A number of volatile hydrocarbons, including toluene, propellants, refrigerants, and volatile nitrites, are commonly abused by inhalation. Some of these substances, principally the halogenated hydrocarbons (which contain a chlorine, bromine, or fluorine), can sensitize the myocardium to the effects of endogenous catecholamines. This can result in dysrhythmias and "sudden sniffing death." Chronic abuse of these agents can lead to cerebral atrophy, neuropsychologic changes, peripheral neuropathy, and kidney disease (see Chapter 114).

Clinical and Laboratory Manifestations. Transient, mild CNS depression is common after hydrocarbon ingestion or inhalation. Aspiration is characterized by coughing, which usually is the first clinical finding. Chest radiographs may initially be normal, but they often show abnormalities within 6 hr of exposure in patients who have aspirated. Respiratory symptoms can remain mild or progress rapidly to ARDS and respiratory failure. Fever and leukocytosis are common accompanying signs in patients with pneumonitis and don't necessarily

imply bacterial superinfection. Chest radiographs can remain abnormal long after the patient is clinically normal. Pneumatoceles can appear on the chest radiograph 2-3 wk after exposure.

After inhalational exposures to halogenated hydrocarbons, patients can present with ventricular dysrhythmias, often refractory to conventional management. Recurrent inhalation of the aromatic hydrocarbon toluene can lead to a type IV renal tubular acidosis.

Treatment. Emesis and lavage are contraindicated given the risk of aspiration. Activated charcoal is not useful because it does not bind the common hydrocarbons and can also induce vomiting. If hydrocarbon-induced pneumonitis develops, respiratory treatment is supportive (see Chapter 397). Neither corticosteroids nor prophylactic antibiotics have shown any clear benefit. Standard mechanical ventilation, high-frequency ventilation, and extracorporeal membrane oxygenation have all been used to manage the respiratory failure and ARDS associated with severe hydrocarbon-induced pneumonitis.

Patients with dysrhythmias in the setting of halogenated hydrocarbon inhalation should be treated with β blockers (usually esmolol) to block the effects of endogenous catecholamines on the sensitized myocardium.

Toxic Alcohols

Methanol is commonly found in windshield washer fluids, deicers, paint removers, fuel additives, liquid fuel canisters, and industrial solvents. *Ethylene glycol* is commonly found in antifreeze. Unintentional ingestion is the most common exposure in children, and small-volume ingestions of concentrated products can theoretically cause toxicity. The pathophysiology, acid–base derangements, and treatment of both chemicals are similar, although they differ in their primary end-organ toxicity. In both cases, the metabolites of the parent compounds are responsible for the serious clinical effects that can follow exposure.

Isopropyl alcohol (rubbing alcohol, hand sanitizers) causes intoxication similar to that associated with ethanol but can also cause a hemorrhagic gastritis and myocardial depression in massive ingestions. Unlike ethylene glycol and methanol, isopropyl alcohol is metabolized to a ketone and does not cause a metabolic acidosis. Management is similar to that of ethanol ingestions (see Chapter 114) and is not further discussed here.

Methanol.

Pathophysiology. Methanol is oxidized in the liver by alcohol dehydrogenase to formaldehyde, which is further oxidized to formic acid by aldehyde dehydrogenase. Toxicity is caused primarily by formic acid, which inhibits mitochondrial respiration.

Clinical and Laboratory Manifestations. Drowsiness, mild inebriation, nausea, and vomiting develop early after ingestion. The onset of serious effects, including profound metabolic acidosis and visual disturbances, is often delayed for up to 12-24 hr as the parent methanol is undergoing metabolism to its toxic metabolites. This metabolism is further slowed if ethanol has also been ingested, since the liver will preferentially metabolize ethanol. Visual disturbances include blurred or cloudy vision, constricted visual fields, decreased acuity, and the "feeling of being in a snowstorm" appear only after acidosis is well established. These visual defects may be reversible if treated early, but untreated they can lead to permanent blindness. On exam, dilated pupils, retinal edema, and optic disc hyperemia may be noted. Initially, patients have an elevated osmolar gap and then develop an anion gap metabolic acidosis as the parent compound is metabolized to formic acid.

In young children, determining if a significant exposure has occurred is usually difficult based on history. Methanol blood levels are available at some laboratories and should be sent after a concerning exposure. If methanol blood levels are not readily available, estimation of an osmolar gap may be used as a surrogate marker, but a normal osmolar gap does not rule out ingestion of any alcohol. Serum osmolality is measured by the freezing point depression method and compared with a calculated serum osmolarity.

Treatment. Treatment is as discussed for ethylene glycol toxicity.

Ethylene Glycol.

Pathophysiology. Ethylene glycol is oxidized by alcohol dehydrogenase in the liver to glycoaldehyde, which is further converted to glycolic acid by aldehyde dehydrogenase. Glycolic acid is responsible for the metabolic acidosis, and is further metabolized to glyoxylic and then to oxalic acid. Oxalic acid combines with serum and tissue calcium, forming calcium oxalate crystals that deposit throughout the body, especially in the renal parenchyma, leading to acute tubular necrosis.

Clinical and Laboratory Manifestations. Early symptoms include nausea, vomiting, CNS depression, and inebriation. Delayed manifestations include an anion gap metabolic acidosis, hypocalcemia, and acute kidney injury. Even later, patients can develop cranial nerve palsies.

Both ethylene glycol and methanol are capable of producing profound, life threatening metabolic acidosis and acidemia, with measured serum bicarbonates that may even be nondetectable. The onset of the acidosis is delayed up to 4-12 hr after ethylene glycol ingestion, and may be delayed further with any concomitant ingestion of ethanol. Ethylene glycol blood concentrations are technically difficult to perform and are available only at some larger reference laboratories. In the absence of readily available ethylene glycol concentrations, calculation of the osmolar gap may be helpful as a surrogate marker.

Examination of the urine with a Wood lamp is neither sensitive nor specific for ethylene glycol ingestion. The earliest sign on a urinalysis of ethylene glycol poisoning is usually hematuria. Calcium oxalate crystals can be seen on urine microscopy but might not be evident early after exposure. Electrolytes (including calcium), acid–base status, kidney function, and ECG should be closely monitored in poisoned patients.

Treatment. Because methanol and ethylene glycol are rapidly absorbed, gastric decontamination is generally not of value. The classic antidote for methanol and ethylene glycol poisoning was ethanol, a preferential substrate for alcohol dehydrogenase, thus preventing the metabolism of parent compounds to toxic metabolites. *Fomepizole* (see Table 63-7), a potent competitive inhibitor of alcohol dehydrogenase, has almost entirely replaced the use of ethanol owing to its ease of administration, lack of CNS and metabolic effects, and overall excellent patient tolerability profile. As with all poisons, a serum concentration must be interpreted along with the time removed from exposure. A patient with a methanol level of 20 mg/dL 24 hr after exposure had a much larger dose than a patient with the same level only 1 hr after ingestion. Indications for fomepizole include ethylene glycol or methanol level >20 mg/dL, history of potentially toxic ingestion (e.g., any intentional overdose), or history of ingestion with evidence of acidosis. There are few disadvantages to giving the initial dose of fomepizole to patients with a concerning history of ingestion or lab findings, and given the dosing schedule of fomepizole (every 12 hr), this strategy buys the clinician time to confirm or exclude the diagnosis before giving a second dose. Adjunctive therapy includes folate (methanol toxicity), pyridoxine (ethylene glycol toxicity) and sodium bicarbonate infusions for both (if acidemic). If a child has had an unintentional exposure and a level of the alcohol cannot be obtained, a reasonable approach is to follow serum chemistries every 4 hr until the child is 12 hr removed from the exposure. If the bicarbonate level on the chemistry panel does not fall in that time frame, then a toxic exposure is unlikely (assuming no ethanol is present).

Hemodialysis effectively removes ethylene glycol, methanol, and their metabolites (except calcium oxalate) and corrects acid–base and electrolyte disturbances. Fomepizole should be given both before and immediately after dialysis. Indications for dialysis include a methanol level of >50 mg/dL, acidosis, severe electrolyte disturbances, and renal failure. However, in the absence of acidosis and kidney failure, even massive ethylene glycol ingestions have been managed without dialysis. Methanol is another story, because its elimination in the setting of alcohol dehydrogenase inhibition is very prolonged, thus often warranting dialysis to remove the parent compound. Therapy (fomepizole and/or dialysis) should be continued until ethylene glycol and methanol levels are <20 mg/dL. While the visual effects from

methanol poisoning are usually permanent, the kidney injury from ethylene glycol injury is not. Patients requiring hemodialysis after ethylene glycol poisoning will almost always recover complete renal function within 2-6 wk. Consultation with a poison control center, medical toxicologist, and nephrologist may be helpful in managing toxic alcohol ingestions.

Plants

Exposure to plants, both inside the home and outside in backyards and fields, is one of the most common causes of unintentional poisoning in children. Fortunately, the majority of ingestions of plant parts (leaves, seeds, flowers) result in either no toxicity or mild, self-limiting effects. However, ingestion of certain plants (Table 63-12 outlines some of the most toxic plants) can lead to serious toxicity.

The potential toxicity of a particular plant is highly variable, depending on the part of the plant involved (flowers are generally less toxic than the root or seed), the time of year, growing conditions, and the route of exposure. Assessment of the potential severity after an exposure is also complicated by the difficulty in properly identifying the plant. Many plants are known by several common names, which can vary among communities. Poison control centers have access to professionals who can assist in properly identifying plants. They also are well versed in the common poisonous plants in their service area and the seasons when they are more abundant. For these reasons, consultation with the local poison control center may be very helpful in the management of these ingestions.

For potentially toxic plant ingestions, consider decontamination with activated charcoal in patients who present within 1-2 hr of ingestion; otherwise, treatment is primarily supportive and based on symptoms. The most common manifestation of toxicity after plant ingestion is GI upset, which can be managed with antiemetics and fluid and electrolyte support. Table 63-12 outlines management strategies for a few specific toxicities.

Toxic Gases

Carbon Monoxide

Although many industrial and naturally occurring gases pose a health risk by inhalation, the most common gas involved in pediatric exposures is carbon monoxide (CO). CO is a colorless, odorless gas produced during the combustion of any carbon-containing fuel. The less efficient the combustion, the greater the amount of CO produced. Wood-burning stoves, kerosene heaters, old furnaces or hot water heaters and automobiles are a few of the potential sources of CO, as is any closed space fire.

Pathophysiology. CO binds to hemoglobin with an affinity >200 times that of oxygen, forming carboxyhemoglobin (HbCO). In doing so, CO displaces oxygen and creates a conformational change in hemoglobin that impairs the delivery of oxygen to the tissues, leading to tissue hypoxia. HbCO levels are not well correlated with clinical signs of toxicity, likely because CO interacts with multiple proteins in addition to hemoglobin. CO binds to cytochrome oxidase, disrupting cellular respiration. CO displaces nitric oxide (NO) from proteins, allowing NO to bind with free radicals to form the toxic metabolite peroxynitrite. NO is also a potent vasodilator, in part responsible for clinical symptoms including headache, syncope, and hypotension.

Clinical and Laboratory Manifestations. Early symptoms are nonspecific and include headache, malaise, nausea, and vomiting. These symptoms are often misdiagnosed as indicating flu or food poisoning. At higher exposure levels, patients can develop mental status changes, confusion, ataxia, syncope, tachycardia, and tachypnea. Severe poisoning is manifested by coma, seizures, myocardial ischemia, acidosis, cardiovascular collapse, and potentially death. On exam, patients might have cherry-red skin. Emergency department evaluation should include an arterial or venous blood gas with HbCO determined by co-oximetry, and creatine kinase in severely poisoned patients, and an ECG in any patient with cardiac symptoms.

Treatment. In addition to general supportive care, treatment requires the administration of 100% oxygen to enhance elimination of CO. In ambient air, the average half-life of HbCO is 4-6 hr. This is dramatically reduced to 60-90 min by providing 100% oxygen at normal atmospheric pressures via a non-rebreather facemask. Severely poisoned patients might benefit from *hyperbaric oxygen (HBO),* which decreases the half-life of HbCO to 20-30 minutes. Though the clinical benefits and referral guidelines for HBO therapy remain controversial, commonly cited indications include syncope, coma, seizure, altered mental status, acute coronary syndrome, HbCO level >25%, abnormal cerebellar examination, and pregnancy. Consultation with a poison control center, medical toxicologist, or HBO facility can assist clinicians in determining which patients could benefit from HBO therapy. Sequelae of CO poisoning include persistent and delayed cognitive and cerebellar effects. HBO advocates believe that the risk of such sequelae is minimized through the delivery of 100% oxygen at 3 atmospheres of pressure. Patients are typically treated with oxygen, via either non-rebreather or a hyperbaric chamber, for between 6 and 24 hr. Prevention of CO poisoning should involve educational initiatives and the use of home CO detectors.

Hydrogen Cyanide

Pathophysiology. Cyanide inhibits cytochrome oxidase, part of the electron transport chain, interrupting cellular respiration and leading to profound tissue hypoxia. Patients may be exposed to hydrogen cyanide gas in the workplace (manufacturing of synthetic fibers, nitriles, and plastics) or via smoke inhalation in a fire.

Clinical and Laboratory Manifestations. Onset of symptoms is rapid after a significant exposure. Clinical manifestations of toxicity include headache, agitation and confusion, sudden loss of consciousness, tachycardia, cardiac dysrhythmias, and metabolic acidosis. Cyanide levels can be measured in whole blood, but they are not readily available at most institutions. A severe lactic acidosis (lactate >10 mmol/L) in fire victims suggests cyanide toxicity. Impaired oxygen extraction by tissues is implied by elevated mixed venous oxygen saturation, another laboratory finding suggesting cyanide toxicity.

Treatment. Treatment includes removal from the source of exposure, rapid administration of high concentrations of oxygen, and antidotal therapy. The cyanide antidote kit includes nitrites (amyl nitrite and sodium nitrite) used to produce methemoglobin, which then reacts with cyanide to form cyanomethemoglobin (see Table 63-7). The third part of the kit is sodium thiosulfate, given to hasten the metabolism of cyanomethemoglobin to hemoglobin and the less-toxic thiocyanate. In patients for whom induction of methemoglobinemia could produce more risk than benefit, the sodium thiosulfate component of the kit may be given alone. The FDA has approved *hydroxocobalamin* (a form of vitamin B_{12}) for use in known or suspected cyanide poisoning. This antidote reacts with cyanide to form the nontoxic cyanocobalamin, which is then excreted in urine. Side effects of hydroxocobalamin include red discoloration of the skin and urine, transient hypertension, and interference with colorimetric lab assays. *Overall, the safety profile of hydroxocobalamin appears superior to that of the cyanide antidote kit; thus this is now the preferred antidote for cyanide poisoning.*

Some Miscellaneous Toxic Agents Found in the Home

Single-Use Detergent Sacs

Commonly known as laundry "pods" for clothing, these products look like candy to many children. When bitten into, a relatively large dose of concentrated detergent is expelled under pressure onto the child's posterior pharynx and vocal cords. This can lead to stridor and other signs of respiratory distress. Occasionally, and for unknown reasons, these children may also develop altered mental status. Supportive care with attention to any airway and breathing issues is warranted. Admission to the hospital is often indicated. It should be noted, that these are not considered caustic ingestions. The pH of these products is in the neutral zone. As such, upper GI endoscopy is rarely indicated. Curiously, laundry detergent drank from a bottle is rarely of significant concern.

Table 63-12 Commonly Ingested Plants with Significant Toxic Potential

PLANT	SYMPTOMS	MANAGEMENT
Autumn crocus (*Colchicum autumnale*)	Vomiting Diarrhea Initial leukocytosis followed by bone marrow failure Multisystem organ failure	Activated charcoal decontamination Aggressive fluid resuscitation and supportive care
Belladonna alkaloids: jimson weed (*Datura stramonium*) Belladonna ("deadly nightshade"; *Atropa belladonna*)	Anticholinergic toxidrome Seizures	Supportive care, benzodiazepines Consider physostigmine if patient is a threat to self or others; only use if no conduction delays on ECG
Cardiac glycoside–containing plants (foxglove, lily of the valley, oleander, yellow oleander, etc)	Nausea Vomiting Bradycardia Dysrhythmias (AV block, ventricular ectopy) Hyperkalemia	Digoxin-specific Fab fragments
Jequirity bean and other abrin-containing species (e.g., rosary pea, precatory bean)	Oral pain Vomiting Diarrhea Shock Hemolysis Renal failure	Supportive care, including aggressive volume resuscitation and correction of electrolyte abnormalities
Monkshood (*Aconitum* species)	Numbness and tingling of lips/tongue Vomiting Bradycardia	Atropine for bradycardia Supportive care
Oxalate-containing plants: *Philodendron, Dieffenbachia, Colocasia* ("elephant ear")	Local tissue injury Oral pain Vomiting	Supportive care, pain control
Poison hemlock *(Conium maculatum)*	Vomiting Agitation followed by CNS depression Paralysis Respiratory failure	Supportive care
Pokeweed	Hemorrhagic gastroenteritis Burning of mouth and throat	Supportive care
Rhododendron	Vomiting Diarrhea Bradycardia	Atropine for symptomatic bradycardia Supportive care
Tobacco	Vomiting Agitation Diaphoresis Fasciculations Seizures	Supportive care
Water hemlock (*Cicuta* species)	Abdominal pain Vomiting Delirium Seizures	Supportive care, including benzodiazepines for seizures
Yew (*Taxus* species)	GI symptoms QRS widening Hypotension CV collapse	Supportive care Atropine for bradycardia Sodium bicarbonate does not appear to be effective

AV, atrioventricular; CNS, central nervous system; CV, cardiovascular; ECG, electrocardiogram; Fab, fragment, antigen binding; GI, gastrointestinal.

Electric Dishwasher Detergent

Especially when in the form of crystals, these products are highly alkaline (pH >13) and exposure via ingestion can lead to significant burns to the vocal cords and GI tract. Admission for upper GI endoscopy is usually indicated.

Magnets

Most foreign body ingestions are allowed to pass through the GI tract once they are known to have passed into the stomach. However, ingestion of 2 or more magnets (unless they are very weak refrigerator style magnets) cause concern for bowel obstruction and/or perforation. Admission for attempted retrieval via endoscopy or clearance via WBI is to be considered.

Batteries

Any disk or button style battery lodged in the esophagus or airway should be considered a true emergency warranting immediate referral to an endoscopist for removal. These batteries can cause necrosis of the tissues to which they are lodged via continued electrical discharge and/or leaking of their contents (the former is likely the primary method of injury). Mucosal contact for even 2 hr might induce necrosis. Once past the lower esophageal sphincter, button or even larger batteries (e.g., AA, AAA size) can usually be allowed to pass through the GI tract with close follow up.

Chapter 64

Complementary Therapies and Integrative Medicine

Kathi J. Kemper and Paula M. Gardiner

Integrative medicine focuses on promoting physical, mental, emotional, spiritual, social, educational, and occupational well-being in the context of a medical home in a healthy family and community. The foundations of integrative medicine are health-promoting practices including optimal nutrition and dietary supplements to avoid deficiencies; avoiding intake of addictive substances such as nicotine and illicit drugs; physical activity, adequate sleep, a healthy environment, and supportive social relationships. Evidence-based complementary therapies such as herbal remedies and other dietary supplements, massage, chiropractic, and other forms of bodywork, yoga, tai chi, meditation practices, hypnosis, guided imagery, biofeedback, and acupuncture may also be used. Although prayer and healing rituals are sometimes included under the rubric of complementary and integrative therapies, they are not covered in this chapter.

Not including multivitamins and mineral supplements (such as iron and calcium), the estimated prevalence of complementary and alternative medicine use in the United States by youth younger than 18 yr of age in 2007 was 8.7 million; the most common therapies included natural products, chiropractic, and deep breathing. Use of complementary therapies is most common among youth with chronic, incurable, or recurrent conditions such as asthma, autism, cancer, depression, and pain. For example, complementary therapies were used by 42-71% of pediatric patients in a 2013 study of specialty outpatient clinics in Canada; the therapies most commonly used by these patients were dietary supplements. Side effects were uncommon and most were minor.

Table 64-1 Most Commonly Used Dietary Supplements in Pediatrics

PRODUCT	USES
VITAMINS	
B_2 (riboflavin)	Migraine headache prophylaxis
B_6 (pyridoxine)	Pyridoxine-dependent epilepsy; neuropathy; nausea associated with pregnancy
B_9 (folate)	Prevention of neural tube defects
D	Prevention of rickets; treatment of deficiencies
Multivitamins	General health promotion, ADHD
MINERALS	
Iodine (salt)	Prevent goiter and mental retardation
Iron	Prevent and treat iron deficiency
Magnesium	Constipation, asthma, migraine prevention
Zinc	Diarrhea in nutrient-poor populations
HERBS	
Aloe vera	Mild burns
Chamomile	Mild sedative, dyspepsia
Echinacea	Prevention of upper respiratory infections
Ginger	Nausea
Lavender (aromatherapy)	Mild sedative
Peppermint	Irritable bowel syndrome
Tea tree oil	Anti-bacterial (acne remedies), pediculicide (lice)
OTHER	
Melatonin	Insomnia
Omega-3 fatty acids (fish oil)	ADHD, allergies, inflammation, anxiety and mood disorders
Probiotics	Antibiotic-associated diarrhea; *Clostridium difficile*–associated diarrhea; constipation; irritable bowel syndrome; pouchitis; inflammatory bowel disorders

ADHD, attention-deficit/hyperactivity disorder.

DIETARY SUPPLEMENTS

Under the 1994 Dietary Supplement Health and Education Act, a dietary supplement is a product taken by mouth that contains a *dietary ingredient* intended to supplement the diet. These may include vitamins, minerals, herbs or other botanicals, amino acids, and substances such as enzymes, organ tissues, glandulars, and metabolites. Dietary supplements are the most commonly used complementary therapies for children and adolescents (Table 64-1). Some uses are common and recommended, such as vitamin D supplements for breastfed infants and probiotics to prevent *Clostridium difficile*–associated diarrhea, whereas other uses are more controversial, such as using herbal products to treat otitis media.

In the United States, dietary supplements do not undergo the same stringent evaluation and postmarketing surveillance as prescription medications. Although they may not claim to prevent or treat specific medical conditions, product labels may make *structure–function* claims. For example, a label may claim that a product *promotes a healthy immune system*, but it may not claim to cure the common cold.

According to the 2007 National Health Interview Survey, 37% of children in the United States used dietary supplements, with the majority using multivitamin and mineral products (31%) exclusively. Use of dietary supplements is most common among children whose families have higher income and education and whose parents use them; among older children; and among those suffering from chronic conditions.

Despite this widespread use, many patients and their parents who use dietary supplements do not talk with their physician about their use. Several guidelines have called for more complete dietary supplement history taking by healthcare professionals. The Joint Commission recommends that clinicians routinely ask patients about their use of dietary supplements and include this information as part of the medication reconciliation process.

DIETARY SUPPLEMENT SAFETY

Dietary supplements may have safety issues in children, though toxicity is much less common with nonprescription dietary supplements than with prescription medications. Toxicity depends on dose, use of cotherapies, and the underlying medical condition of the child. Modern use of a dietary supplement (e.g., ephedra for weight loss) may not reflect its traditional use (e.g., ephedra as a component of a traditional Chinese medicine tea in small doses to improve allergic or respiratory symptoms). Moreover, herbs that are apparently safe for most adults may be more hazardous in specific conditions (e.g., newborns, patients with impaired renal or hepatic function), under special circumstances (e.g., after organ transplantation or other surgery), or when combined with prescription medications. Some natural products are toxic in and of themselves (Table 64-2). Acute hepatic toxicity and death can result from ingestion of even small amounts of *Amanita* mushrooms. Even when a product is safe when used correctly, it can cause mild or severe toxicity when used incorrectly. Although peppermint is a commonly used and usually benign gastrointestinal spasmolytic included in after-dinner mints, it can exacerbate gastroesophageal reflux. Probiotics are generally safe when taken orally, but in an immune-compromised patient in an ICU setting, they may (rarely) cause sepsis.

Table 64-2 Potentially Toxic Herbs

HERB	TOXIC CONSTITUENTS	TYPICAL USES	POTENTIAL ACUTE ADVERSE EFFECTS	HOW TO TREAT OVERDOSE
Aconitum (monkshood, wolfsbane)	**Diester alkaloids:** Hypaconitine and aconitine (aconitine increases permeability for sodium ions and slows down repolarization, leading to paralysis of the nerve)	Facial neuralgia and sciatica Headache and migraines Rheumatic pain, arthritis, gout Pericarditis sicca	Nausea, vomiting, hypersalivation **CNS:** Paresthesias, muscular weakness, dizziness, ataxia, seizures, coma **Cardiac:** Bradycardia, hypotension, rhythm disorders	Supportive care Dioxin-specific antibodies, unless history excludes cardiac glycosides Do not give ipecac Activated charcoal and gastric emptying might help Avoid type 1 antiarrhythmics
Artemisia absinthium (wormwood)	**Thujone and isothujone:** Neurotoxins	Anorexia Dyspeptic conditions Liver and gallbladder disorders	**Mental status changes:** Restlessness, vertigo, tremors, agitation, seizures, headache Vomiting; stomach and intestinal cramps Rhabdomyolysis and renal failure	Supportive care Benzodiazepines
Atropa belladonna (deadly nightshade) of atropine)	**Alkaloids:** Hyoscyamine (the L-isomer)	Gastrointestinal symptoms Cardiac insufficiency and arrhythmia Asthma	**Anticholinergic reaction:** Tachycardia, hyperthermia, mydriasis, urine and feces retention, restlessness Nervous system and respiratory depression	Gastric lavage Physostigmine given in consultation with a poison specialist External cooling if temperature is >38.9°C (102°F) Benzodiazepines Hydration
Ayurvedic herbal remedies	Contaminated with lead, mercury, or arsenic	Traditional medicine from India; many purposes	Acute or chronic heavy metal toxicity	Depends on heavy metal
Digitalis purpurea (foxglove)	**Cardioactive glycosides:** Purpurea glycoside, digitoxin	Ulcers, boils, headaches, abscesses, paralysis, cardiac insufficiency	Nausea and vomiting, headache, loss of appetite Cardiac rhythm disorders **CNS:** Stupor, confusion, visual disorders, depression, psychosis, hallucinations	Supportive care Gastric lavage Activated charcoal Treatment of symptoms
Ephedra sinica (ma huang) Common names: Miner's tea, Mexican tea, Desert herb	**Alkaloids:** Ephedrine, pseudoephedrine (stimulates sympathomimetic receptors and the CNS)	Decongestant for upper respiratory infection Asthma Weight loss Stimulant	**Cardiac:** Hypertension, cardiomyopathy, myocardial infarction, arrhythmias **CNS:** Dizziness, restlessness, headaches, anxiety, hallucinations, tremors, seizures, psychosis, strokes Nausea and vomiting Contraindicated in diabetes or hypertension, angle-closure glaucoma, anxiety, prostate adenoma, thyroid disease, pheochromocytoma	Activated charcoal Benzodiazepine for seizures and sedation Vasodilators for hypertension Lidocaine and β blockers for arrhythmias External cooling if temperature is >38.9°C (102°F) Hydration therapy
Illicium anisatum (Japanese star anise tea)	Anisatins; block γ-aminobutyric acid	Colic in Latino and Caribbean populations	Seizures, tonic postures, myoclonus, hyperexcitability, irritability	Recovery with supportive care within 48 hr
Lobelia inflata (lobelia)	**Piperidine alkaloid:** L-Lobeline (stimulates nicotinic receptors)	Expectorant Asthma Spasmolytic Emetic To induce mental clarity and a feeling of well-being	**Gastrointestinal:** Nausea and vomiting, abdominal pain, diarrhea **CNS:** Anxiety, headache, dizziness, tremors, seizures, paresthesias, euphoria **Cardiac:** Arrhythmias, bradycardia, transient increase in blood pressure, decreased respiratory rate In overdose, lobeline can cause hypotension. Diaphoresis, muscle fasciculations and weakness, tremors, respiratory depression Dermatitis	Supportive care Gastric emptying Activated charcoal Benzodiazepines

Continued

Table 64-2 Potentially Toxic Herbs—cont'd

HERB	TOXIC CONSTITUENTS	TYPICAL USES	POTENTIAL ACUTE ADVERSE EFFECTS	HOW TO TREAT OVERDOSE
Longdan xieganwan	Aristolochic acid	Enhance health	Renal interstitial fibrosis End-stage renal failure Renal cell carcinoma	Supportive care
Mentha pulegium (pennyroyal)	Pennyroyal oil has a hepatotoxic effect Acute poisoning is not found with proper administration of the designated therapeutic use of pennyroyal leaf; however, the drug is not recommended owing to hepatotoxicity	Insect repellent Respiratory illness Digestive disorders Emmenagogue Abortifacient Wound treatment Gout	Uterine contractions **Gastrointestinal:** Nausea, vomiting, abdominal pain, hepatitis **Neurotoxin:** Delirium, dizziness, convulsions, seizures, paralysis, encephalopathy, coma Renal failure and hypertension Shock and disseminated intravascular coagulation Contraindicated in pregnancy	Supportive care *N*-Acetylcysteine
Pausinystalia yohimbe (yohimbe)	Indole alkaloids **Yohimbe:** α_2-Adrenoreceptor antagonist	Sexual disorders Exhaustion Improve muscle function	**Adverse reactions:** Dizziness, headache, anxiety, hypertension, indigestion, rash, insomnia, tachycardia, tremor, vomiting, hallucinations, nervousness, paresthesias, hypothermia, salivation, mydriasis, diarrhea, palpations, tachycardia Contraindicated in kidney and liver disease	Gastric emptying Activated charcoal Antiarrhythmics Hydration
Phytolacca americana (pokeweed, American nightshade)	Triterpene saponins (irritate mucous membranes) Lectins (toxic)	Antiinflammatory Arthritis Cancer Emetic and cathartic Rheumatism	Dizziness, somnolence, nausea, vomiting, diarrhea, tachycardia, hemorrhagic gastritis, hypotension, lymphocytosis, headache, respiratory depression, seizures	Hydration therapy, electrolyte correction, gastric emptying Activated charcoal Electrolyte replacement Emesis should not be induced if patient is experiencing symptoms of overdose
Stramonium folium (jimsonweed)	**Alkaloids:** Hyoscyamine (the L-isomer of atropine)	Asthma and cough Diseases of the autonomic nervous system	In high doses, leads to restlessness, mania, hallucinations, delirium **Overdose:** Tachycardia, mydriasis, flushing, dry mouth, decreased sweating, miction, constipation	Supportive care Gastric lavage Decreasing temperature Physostigmine Benzodiazepines
Viscum album (mistletoe)	Alkaloids Viscotoxins *(Viscum album)* cause hypotension, bradycardia, and arterial vasoconstriction Lectins	Antineoplastic adjuvant Antihypertensive Nervous disorders: calmative agent Rheumatism Antispasmodic	Fever, headaches, nausea, vomiting, diarrhea, bradycardia, angina, change in blood pressure, seizures, confusion, hallucination, allergic reactions, miosis, mydriasis, chills, coma 2 reported deaths in the last 35 yr; most ingestions lead to mild reactions	Supportive therapy Data inconclusive for inducing emesis Activated charcoal

CNS, central nervous system.

Although there are good manufacturing practices for dietary supplements in the United States, dietary supplement labels might not accurately reflect the contents or concentrations of ingredients. Because of natural variability, variations of 10-1,000–fold have been reported for several popular herbs, even across lots produced by the same manufacturer. Herbal products may be unintentionally contaminated with pesticides, microbial agents or products, or the wrong herb that was misidentified during harvesting. Products from developing countries (e.g., Ayurvedic products from South Asia) might contain toxic levels of mercury, cadmium, arsenic, or lead, either from unintentional contamination during manufacturing or from intentional additions by producers who believe that these metals have therapeutic value. Approximately 30-40% of Asian patent medicines include potent pharmaceuticals, such as analgesics, antibiotics, hypoglycemic agents, or corticosteroids; typically, the labels for these products are not written in English and do not note the inclusion of pharmaceutical agents. Even conventional mineral supplements, such as calcium, have been contaminated with lead or had significant problems with product variability.

Many families use supplements concurrently with medications, posing hazards of interactions (Table 64-3). St. John's wort induces CYP3A4 activity of the P450 enzyme system and thus can enhance elimination of most drugs, including digoxin, cyclosporine, protease inhibitors, oral contraceptives, and numerous antibiotics, leading to

Table 64-3 The HDS–Drug Interactions with Major Severity* (Other Than St. John's Wort)

HDS	DRUGS	POTENTIAL CONSEQUENCES/ REACTIONS†
5-Hydroxytryptophan	Fluoxetine, fluvoxamine, paroxetine, sertraline, venlafaxine	↑Risk of serotonin syndrome
Acacia	Amoxicillin	↓Absorption of amoxicillin
Alfalfa	Warfarin	↓The effect of warfarin
Aloe vera	Digoxin	↑Digoxin toxicity
American ginseng	Warfarin	↓The effect of warfarin
Arginine	Enalapril, nitroglycerin	↑Hypotensive effects
	Spironolactone	↑Risk of hyperkalemia
Bitter orange	Phenelzine	↑Risk of hypertensive crisis
Cowhage	Methyldopa	↑Hypotensive effects
Danshen	Aspirin, ticlopidine, warfarin	↑Risk of bleeding
	Digoxin	↑Digoxin toxicity
Digitalis	Bendroflumethiazide, chlorothiazide, chlorthalidone, hydrochlorothiazide, hydroflumethiazide, indapamide, methyclothiazide, metolazone, polythiazide, trichlormethiazide	↑Digoxin toxicity
	Digoxin	↑Digoxin toxicity
Dong quai	Aspirin, heparin, ticlopidine, warfarin	↑Risk of bleeding
Evening primrose	Warfarin	↑Risk of bleeding
Garlic	Ritonavir	↓The effect of ritonavir
	Saquinavir	↓The effect of saquinavir
	Warfarin	↑Risk of bleeding
Ginkgo	Aspirin, cilostazol, clopidogrel, dipyridamole, heparin, ibuprofen, naproxen, ticlopidine, warfarin	↑Risk of bleeding
	Risperidone	↑Risk of risperidone adverse effects
	Trazodone	Excessive sedation and potential coma
Glucosamine	Warfarin	↑Risk of bleeding
Green tea	Ephedrine	↑Risk of stimulatory adverse effects
Guarana	Ephedrine	↑Risk of stimulatory adverse effects
Hawthorn	Digoxin	↑Digoxin toxicity
Henbane	Chlorpheniramine, clemastine, dimenhydrinate, diphenhydramine, doxylamine, promethazine	↑Risk of anticholinergic side effects
Kava	Alprazolam, chlordiazepoxide, clonazepam, diazepam, estazolam, flurazepam, lorazepam, midazolam, morphine, oxazepam, phenobarbital, quazepam, temazepam, triazolam	↑Central nervous system depression
	Droperidol	↑Central nervous system depression
Licorice	Warfarin	↑Risk of bleeding
L-Tryptophan	Citalopram, duloxetine, fluoxetine, fluvoxamine, isocarboxazid, paroxetine, phenelzine, selegiline, sertraline, sibutramine, tranylcypromine, venlafaxine	↑Risk of serotonin syndrome
	Zolpidem	↑Zolpidem-induced side effect
Melatonin	Zolpidem	↑Sedative effects
N-Acetylcysteine	Nitroglycerin	Severe hypotension, intolerable headaches
Niacin	Atorvastatin, cerivastatin, lovastatin, rosuvastatin, simvastatin	↑Risk of myopathy or rhabdomyolysis
PABA	Dapsone, Sulfamethoxazole	↓Antibacterial effect
Pleurisy root	Digoxin	↑Digoxin toxicity
Potassium	Amiloride, benazepril, captopril, enalapril, fosinopril, indomethacin, lisinopril, moexipril, quinapril, ramipril, spironolactone, trandolapril, triamterene	↑Risk of hyperkalemia
Red yeast rice	Cyclosporine	↑Creatine phosphokinase values
S-Adenosylmethionine	Clomipramine	↑Risk of serotonin syndrome
Scotch broom	Haloperidol	↑The potential toxicity
	Phenelzine	↑Risk of hypertensive crisis
Valerian	Alprazolam, phenobarbital	↑Central nervous system depression

subtherapeutic serum levels. In contrast, St. John's wort may *enhance* the risk of the serotonin syndrome in patients on selective serotonin reuptake inhibitor agents, increase the sedation of opioids, increase the photosensitivity reactions of certain drugs, and increase the toxicity of propofol and sevoflurane.

Many folk medicine are named based on their natural language (Tables 64-4 and 64-5), which must be taken into consideration when treating specific ethnic populations.

DIETARY SUPPLEMENT EFFICACY

Evidence about the effectiveness of dietary supplements to prevent or treat pediatric problems is mixed, depending on the product used and condition treated. Some herbal products may be helpful adjunctive treatments for common childhood problems; some herbs have proved helpful for colic (fennel and the combination of chamomile, fennel, vervain, licorice, and balm mint), nausea (ginger), irritable bowel syndrome (peppermint), and diarrhea (probiotics).

MASSAGE AND CHIROPRACTIC

Massage is commonly provided at home by parents and by professional massage therapists, physical therapists, and nurses in clinical settings. Infant massage is routinely provided in many neonatal intensive care units to promote growth and development in preterm infants. Massage also has been demonstrated to be beneficial for pediatric patients suffering from asthma, insomnia, colic, cystic fibrosis, and juvenile ideopathic arthritis. Massage therapy is generally safe. Professional massage practice is regulated by state governments; more than 40 states license massage therapists, and 3 offer statewide independent certification.

More than 50,000 chiropractors are licensed in the United States, including licensure in all 50 states. Chiropractic care is covered by most major insurers. Up to 14% of all chiropractic visits are for pediatric patients, not including care provided by chiropractors working for athletic departments or professional teams. While chiropractic care may be useful for treating minor musculoskeletal injuries, parents need to be cautioned not to rely on chiropractic as the primary treatment for serious conditions, such as neurologic deficits, cancer or autism; data suggest that severe complications are possible.

MIND–BODY THERAPIES

Mind–body therapies such as slow, deep breathing, meditation, guided imagery, biofeedback, hypnosis, tai chi, and yoga, are the second most commonly used group of complementary therapies in pediatrics. These practices can be learned informally through books, YouTube videos, CDs, DVDs, smart phone applications, or classes, or in therapeutic sessions with health professionals, such as psychologists and social workers (Table 64-6). Substantial research suggests that such practices can aid in reducing anxiety, insomnia, and stress-related conditions including migraine headaches and functional abdominal pain. They can also help patients struggling with chronic pain.

Table 64-5 Spanish-English Botanical Name Translation Chart

SPANISH NAME	ENGLISH NAME	BOTANICAL NAME
Ajo	Garlic	*Allium sativum*
Cebolla	Onion	*Allium cepa*
Cenela	Cinnamon	*Cinnamomum aromaticum*
Clavo	Cloves	*Eugenia aromatica*
Comino	Cumin	*Cuminum cyminum*
Epasote or herba Sancti Mariae	Wormseed	*Chenopodium anthelminticum*
Estafiate	Wormwood	*Artemisia absinthium*
Eucalipto	Eucalyptus	*Eucalyptus globulus*
Granada	Pomegranate	*Punica granatum*
Jengibre	Ginger	*Zingiber officinale*
Limon	Lemon	*Citrus limon*
Manzanilla	Chamomile	*Anthemis nobilis* or *Chamomilla recutita* or *Matricaria chamomilla*
Oregano	Oregano	*Origanum vulgare*
Pelos de elote	Corn silk	*Zea mays*
Savila	Aloe vera	*Aloe vera*
Tomillo	Thyme	*Thymus vulgaris*
Una de gato	Cat's claw	*Uncaria tomentosa*
Valeriana	Valerian	*Valeriana officinalis*
Yerba buena	Spearmint	*Mentha spicata*

Table 64-6 Commonly Used Mind–Body Practices in Pediatrics

PRACTICE	USES
Biofeedback	Preventing migraine headaches; reducing stress and anxiety; encopresis/constipation treatment; treatment of stress incontinence; neurofeedback is experimental for ADHD
Deep breathing	Relaxation; stress management
Guided imagery	Stress management, anxiety, pain relief
Hypnosis	Correcting habit disorders; preventing headaches; managing pain
Meditation	Stress management, improving concentration
Tai chi	Improved balance, coordination, concentration, discipline
Yoga	Improved balance, coordination, concentration

ACUPUNCTURE

Modern acupuncture incorporates treatment traditions from China, Japan, Korea, France, and other countries. In the United States, acupuncturists are licensed to practice in 43 states, and acupuncture services are offered by more than 30% of North American academic pediatric pain treatment programs. The technique that has undergone most scientific study involves penetrating the skin with thin, solid, metallic needles manipulated by hand or by electrical stimulation. Variants include rubbing (shiatsu), heat (moxibustion), lasers, magnets, pressure (acupressure), or electrical currents.

Although most pediatric patients are averse to needles, patients who suffer from severe chronic pain or nausea may be amenable to trying acupuncture and often report that it is helpful. Acupuncture can offer significant benefits in the treatment of recurrent headache, anxiety, back and other types of pain, depression, and nausea. As with any therapy involving needles, infections and bleeding can occur, but more serious complications, such as pneumothorax, occur in <1 in 30,000 treatments.

The Acutely Ill Child

PART IX

Chapter 65

Evaluation of the Sick Child in the Office and Clinic

Patrick C. Drayna and Marc H. Gorelick

Acutely ill children pose a challenge to a busy pediatrician's office. Illnesses can span the spectrum from simple viral infections to life-threatening emergencies. Pediatricians need to distinguish between patients who can be managed with close outpatient follow-up and those that need to be stabilized and transported to a higher level of care. Although patients of all ages can present with similar symptoms, the etiology of the illness can be age-dependent. The initial approach must focus on the general evaluation and stabilization of the acutely ill infant and child.

HISTORY

A thorough history is paramount to arriving at the correct diagnosis. Obtaining an accurate history from young patients is challenging, and parents often provide the most important information. On the basis of the chief complaint(s), the pediatrician must ask open-ended questions that help distinguish between common and potentially life-threatening entities. Common complaints leading to acute care visits for potential emergencies include **fever**, **altered mental status**, **vomiting**, **respiratory distress**, and **abdominal pain**.

Fever is the most common reason for a sick child visit. Most fevers are the result of self-limited viral infections. However, pediatricians need to be aware of the age-dependent potential for serious bacterial infections (e.g., urinary tract infections, sepsis, meningitis, pneumonia, dysentery, osteoarticular infection). During the first 2-3 mo of life, the neonate is at risk for sepsis caused by pathogens that are uncommon in older children. These organisms include group B streptococcus, *Escherichia coli, Listeria monocytogenes,* and herpes simplex virus. In neonates, the history must include maternal obstetric information and the patient's birth history. Risk factors for sepsis include maternal group B streptococcus colonization, prematurity, chorioamnionitis, and prolonged rupture of membranes. If there is a maternal history of sexually transmitted infections during the pregnancy, the differential diagnosis must be expanded to include those pathogens. Septic infants can present with lethargy, poor feeding, grunting respirations, and cool or mottled extremities, in addition to fever (or hypothermia). Infants with fever, irritability, and a bulging fontanel should be evaluated for meningitis. As the infant matures beyond 3 mo of age, the bacterial pathogens that usually cause bacteremia, sepsis, and meningitis are *Streptococcus pneumoniae, Haemophilus influenzae* type b, and *Neisseria meningitidis.* Urosepsis secondary to an *E. coli* urinary tract infection also needs to be considered. Immunization against some serotypes of *S. pneumoniae* has markedly reduced the occurrence of occult bacteremia and serious infections caused by that organism, as has immunization against *H. influenzae* type b. These remain potential concerns in those children not fully immunized against these pathogens. Other ailments that manifest with fever include septic arthritis and osteomyelitis, juvenile idiopathic arthritis, and Kawasaki disease. Children with a septic joint generally present with only 1 joint that is painful and often have pseudoparalysis of that joint. In contrast, patients with juvenile rheumatoid arthritis may present with pain, stiffness, swelling, and warmth of several joints. The diagnosis of Kawasaki disease should be considered if the patient meets the diagnostic criteria for this illness although some patients may have an atypical or incomplete presentation (see Chapter 166).

For patients presenting with **altered mental status**, the pediatrician should inquire about the presence of other symptoms, such as fever or headache. Screening questions should be asked regarding feeding changes, medications in the household, or the possibility of trauma. Parents will often describe a febrile child as "lethargic," but further questioning will reveal a tired-appearing child who interacts appropriately when the child has defervesced. Febrile patients need to be differentiated from the lethargic patient who presents with sepsis or meningitis. Infants with meningitis or sepsis may have a history of irritability, inconsolability, poor feeding, grunting respirations, seizures, decreased urine output, and/or color changes such as pallor, mottling, or cyanosis. Patients with poisonings or inborn errors of metabolism can also present with lethargy, poor feeding, unusual odors, seizures, and/or vomiting. Nonaccidental trauma should always be considered in a lethargic infant. Older children may present with altered mental status as a result of meningitis/encephalitis, trauma, or ingestions. Children with meningitis may have a history of fever and complaints of neck pain; other associated symptoms can include rash, headache, photophobia and/or vomiting. Children with ingestions can present with other abnormal neurologic symptoms such as ataxia, slurred speech, seizures, or characteristic constellations of vital sign changes and other physical findings (toxidromes).

Vomiting is a very common complaint of intestinal, other abdominal (e.g., pancreas, liver) or nongastrointestinal (e.g., hyperammonemia, increased intracranial pressure, poisoning) origin and may be a nonspecific sign of systemic illness. Questions to ask include about the presence of bilious or bloody emesis, abdominal distention, weight changes, presence of diarrhea, obstipation or hematochezia, history of trauma, and presence of headache. Although common causes of vomiting are gastroesophageal reflux and viral gastroenteritis, the pediatrician needs to be aware of other serious causes. In the infant, bilious emesis and abdominal distention and/or pain are worrisome for obstruction, as may be seen with malrotation with midgut volvulus or Hirschsprung disease. It is important to consider extraabdominal causes of vomiting in the neonate, including hydrocephalus, incarcerated hernia, inborn errors of metabolism, and nonaccidental trauma. Markedly increasing head circumference or a bulging fontanel can be the result of congenital hydrocephalus or can signal the presence of subdural hematomas from nonaccidental trauma. An infant who appears immediately hungry after projectile vomiting suggests a differential diagnosis of pyloric stenosis. In an older child, the differential diagnosis includes intussusception, incarcerated hernia, diabetic ketoacidosis, appendicitis, poisonings, and trauma. Patients with intussusception may present with vomiting and colicky abdominal pain. A history of increased urination in the presence of vomiting may herald the diagnosis of diabetes mellitus. Patients with headache and vomiting raise a concern for increased intracranial pressure and should be questioned about neurologic changes, meningismus, and fever.

Parents can interpret different symptoms as **respiratory distress**. Tachypnea secondary to fever is often a source of parental anxiety. Parents of newborn infants are sometimes alarmed by the presence of periodic breathing. Normal variations in respiratory patterns must be distinguished from true respiratory distress. Parents need to be questioned regarding associated symptoms such as fever, limitation of neck movement, drooling, choking, and the presence of stridor or wheezing.

A history of apnea or cyanosis warrants further investigation. Although wheezing is often secondary to bronchospasm, it can also be caused by cardiac disease or congenital anomalies such as vascular rings. Infants with congenital heart defects may be tachypneic but may lack any signs of respiratory distress as a compensatory mechanism for shock or metabolic acidosis. Parents often confuse and interpret stridor as wheezing, and care should be taken to differentiate the two. Stridor is most commonly caused by croup. However, anatomic abnormalities such as laryngeal webs, laryngomalacia, subglottic stenosis, and paralyzed vocal cords also cause stridor. Toddlers who present with wheezing or stridor after a coughing or choking episode should be evaluated for a foreign body aspiration. In toxic-appearing children with stridor, the pediatrician should consider epiglottitis, bacterial tracheitis, or a rapidly expanding retropharyngeal abscess. The incidence of epiglottitis has markedly declined with the advent of the *H. influenzae* type b (Hib) vaccine, but remains a possibility in the unimmunized or partially immunized patient. Children with retropharyngeal abscesses may also present with drooling and limitation of neck movement (especially hyperextension) after a recent upper respiratory infection or penetrating mouth injury.

Abdominal pain is another frequent complaint. Often this symptom is caused by a minor illness such as constipation, functional abdominal pain, urinary tract infection, or gastroenteritis. Parents should be questioned about associated symptoms including stooling patterns, abdominal distention, fever, urinary symptoms, and vomiting. In neonates, a tender abdomen is concerning for the presence of a small bowel obstruction; these infants tend to appear ill. There may be a history of vomiting and decreased or no stooling. Pediatricians should be wary of neonates with abdominal tenderness and bloody stools, as 10% of cases of necrotizing enterocolitis occur in term infants. Infants with milk protein intolerance can also present with bloody stools, but these infants are well-appearing and do not have abdominal tenderness. In older patients, the differential diagnosis for a potential emergency with abdominal pain expands to include intussusception and appendicitis. Patients with intussusception can present in a variety of ways, ranging from having episodes of colicky abdominal pain, but otherwise well in between episodes, to being lethargic or in shock. The diagnosis of appendicitis in the child younger than 3 yr is extremely difficult because children in this age group do not localize their pain well. Often the diagnosis is made after the appendix has ruptured.

The child's **past medical history** also needs to be obtained. It is important to be aware of any underlying chronic problems that might predispose the child to recurring infections or a serious acute illness. The child with sickle cell anemia is at increased risk for bacteremia, as well as painful vasoocclusive crisis. A careful review of systems can help in identifying the nature of the acute illness, as well as any complications needing intervention, such as dehydration accompanying an otherwise minor viral illness.

PHYSICAL EXAM

Observation is important in the evaluation of the acutely ill child. Most observational data that the pediatrician gathers during an acute illness should focus on assessing the child's response to stimuli. Do they awaken easily with a stimulus? Do they smile and interact with the examiner? Can the crying child be consoled by the parents' comforting? Assessing responses to stimuli requires knowledge of normal responses for different age groups, the manner in which those normal responses are elicited, and to what degree a response might be impaired. Thus, the pediatrician must be both clinically and developmentally oriented.

During the **physical examination**, the pediatrician seeks evidence of illness. The portions of the physical examination that require the child to be most cooperative are completed first. Initially, it is best to seat the child on the parent's lap; the older child may be seated on the examination table. It is also important to assess the child's willingness to move and ease of movement. It is reassuring to see the child moving about on the parent's lap with ease and without discomfort. Vital signs are often overlooked but are invaluable in assessing ill children. The degree of fever, the presence of tachycardia out of proportion to the fever, and the presence of tachypnea and hypotension all suggest a serious infection. The respiratory evaluation includes determining respiratory rate, the presence or absence of hypoxia by pulse oximetry, and noting any evidence of inspiratory stridor, expiratory wheezing, grunting, coughing, or increased work of breathing (e.g., retractions, nasal flaring, belly breathing). Because acute infections in children are most often caused by viral infections, the presence of nasal discharge may be noted. It is possible at this time to assess the skin for rashes. Frequently, viral infections cause an exanthem and many of these eruptions are diagnostic (e.g., the reticulated rash and "slapped-cheek" appearance of parvovirus infections or the typical appearance of hand-foot-and-mouth disease caused by coxsackieviruses). The skin examination may also yield evidence of more serious infections (bacterial cellulitis or petechiae and purpura associated with bacteremia). Cutaneous perfusion should be assessed by warmth and capillary refill time. When the child is seated and is least perturbed, an assessment of the fontanel can be completed; the examiner can determine whether the fontanel is depressed, flat, or bulging.

During this initial portion of the physical examination, when the child is most comfortable, the heart and lungs are auscultated. In the acutely febrile child, because of the relatively frequent occurrence of respiratory illnesses, it is important to assess adequacy of air entry into the lungs, equality of breath sounds, and evidence of adventitial breath sounds, especially wheezes, rales, and rhonchi. The coarse sound of air moving through a congested nasal passage is frequently transmitted to the lungs. The examiner can become attuned to these coarse sounds by placing the stethoscope near the child's nose and then compensating for this sound as the chest is auscultated. The cardiac examination is next; findings such as pericardial friction rub, loud murmurs, and distant heart sounds may indicate an infectious process involving the heart. The eyes are examined to identify features that might indicate an infectious process. Often, viral infections result in a watery discharge or redness of the bulbar conjunctivae. Bacterial infection, if superficial, results in purulent drainage; if the infection is more deep-seated, tenderness, swelling, and redness of the tissues surrounding the eye are present, as well as proptosis, reduced visual acuity, and altered extraocular movement. The extremities may then be evaluated not only for ease of movement but also for the possibility of swelling, heat, or tenderness; such abnormalities may indicate focal infections.

The components of the physical examination that are more bothersome to the child are completed last. This is best done with the patient on the examination table. Initially, the neck is examined to assess for areas of swelling, redness, or tenderness, as may be seen in cervical adenitis. Resistance to neck movement should prompt evaluation for signs of meningeal irritation (i.e., Kernig and Brudzinski signs) or a retropharyngeal abscess. During examination of the abdomen, the diaper is removed. The abdomen is inspected for distention. Auscultation is performed to assess adequacy of bowel sounds, followed by palpation. The child often fusses as the abdomen is auscultated and palpated. Every attempt should be made to quiet the child; if this is not possible, increased fussing as the abdomen is palpated may indicate tenderness, especially if this finding is reproducible. In addition to focal tenderness, palpation may elicit involuntary guarding or rebound tenderness (including tenderness to percussion); these findings indicate peritoneal irritation, as is seen in appendicitis. The inguinal area and genitals are then sequentially examined. The child is then placed in the prone position, and abnormalities of the back are sought. The spine and costovertebral angle areas are percussed to elicit any tenderness; such a finding may be indicative of vertebral osteomyelitis or diskitis and pyelonephritis, respectively.

Examining the ears and throat completes the physical examination. These are usually the most bothersome parts of the examination for the child, and parents frequently can be helpful in minimizing head movement. During the oropharyngeal examination, it is important to document the presence of enanthemas; these may be seen in many infectious processes, such as hand-foot-and-mouth disease caused by coxsackievirus. This portion of the examination is also important in documenting inflammation or exudates on the tonsils, which may be viral or bacterial.

Repeating portions of the assessment may be indicated. If the child cried continuously during the initial clinical evaluation, the examiner may not be certain whether the crying was caused by the high fever, stranger anxiety, or pain, or is indicative of a serious or localizing illness. Constant crying also makes portions of the physical examination, such as auscultation of the chest, more difficult. Before a repeat assessment is performed, efforts to make the child as comfortable as possible are indicated.

Febrile children can appear very ill, initially appearing listless, tachycardic, and tachypneic. These patients should receive antipyretic medications and be reassessed once they have defervesced. In the majority of children with uncomplicated viral illnesses, the vital signs normalize. Persistence of abnormal vital signs should prompt the clinician to further investigate the source of fever. Continued tachycardia and poor perfusion may be secondary to myocarditis. Tachypnea may be the sole symptom in patients with pneumonia, especially in children whose chief complaint is abdominal pain due to lower lobe pneumonia. Persistent irritability suggests meningitis/encephalitis.

RISK FACTORS

The sensitivity of the carefully performed clinical assessment, observation, history, and physical examination for the presence of serious illness is approximately 90%. If a serious illness is suspected, other data should be sought to improve this sensitivity level. Important supplemental data are age, body temperature, and the results of screening laboratory tests as indicated. Febrile children in the first 3 mo of life have yet to achieve immunologic maturity and therefore are more susceptible to severe infections. Thus, the febrile infant is at greater risk for serious bacterial infection than the child beyond 3 mo of age and warrants careful evaluation. Data from the era before widespread immunization for *H. influenzae* type b and pneumococcus suggest the risk of bacteremia in infants increases as the magnitude of fever increases; it is unclear how this applies today.

Screening laboratory tests may be helpful in identifying the febrile child at increased risk for selected serious illnesses. Practice guidelines from the prevaccine era suggested that white blood cell count might be useful in establishing a higher risk of bacteremia. Because the incidence of occult pneumococcal bacteremia in febrile children has declined significantly as a result of the introduction of conjugated pneumococcal vaccine, the utility of white blood cell count in otherwise healthy febrile young children older than 2-3 mo of age is questionable. Urinalysis and urine culture must always be considered when the source of fever is not apparent, especially in the highest-risk groups: females and uncircumcised males younger than 2 yr of age and all boys younger than 1 yr of age. The presence of leukocyte esterase, >5 white blood cells/high-power field on a spun urine specimen, or bacteria detected by Gram stain on an unspun urine specimen suggests urinary tract infection, but the sensitivity of these indicators is, on average, only 75-85%; urine culture is the definitive test. Procalcitonin, C-reactive protein, and interleukin-6 are being investigated as potential biomarkers of differentiating serious bacterial illness from benign viral disease in children.

MANAGEMENT

Most patients who present to the pediatrician's office with an acute illness will not require resuscitation. However, the pediatrician needs to be prepared to evaluate and begin resuscitation for the seriously ill or unstable child. The pediatrician's office should be stocked with appropriate equipment necessary to stabilize an acutely ill child. Maintenance of that equipment and ongoing training of the office staff in use of the equipment and procedures is required (see Chapter 66). The evaluation must begin with assessment of the ABCs—airway, breathing, and circulation. When assessing the airway, chest rise should be evaluated, and evidence of increased work of breathing sought. The examiner should ensure that the trachea is midline. If the airway is patent and no signs of airway obstruction are present, the patient is allowed to assume a position of comfort. If the child shows signs of airway obstruction, repositioning of the head with the chin-lift maneuver may alleviate the obstruction. An oral or nasal airway may be necessary in patients in whom airway patency cannot be maintained. These devices are not well-tolerated in conscious patients and may induce gagging or vomiting, and instead are most often utilized to facilitate effective bag-valve-mask ventilation. Once airway patency has been established, the adequacy of breathing should be evaluated. Slow respiratory rates or cyanosis may signal respiratory failure. If the airway is patent but the child's respiratory effort is inadequate, positive pressure ventilation via bag-valve-mask should be initiated. Oxygen should be administered to all seriously ill or hypoxic children via nasal cannula or face mask. Auscultation of the lung fields should assess for air entry, symmetry of breath sounds, and presence of adventitious breath sounds such as crackles or wheezes. Bronchodilator therapy can be initiated to alleviate bronchospasm. Racemic epinephrine is indicated for stridor at rest in a patient with croup. Once airway and breathing have been addressed, circulation must be evaluated. This involves assessment of cardiac output. Symptoms of shock include tachycardia, cool extremities, delayed capillary refill time, mottled or pale skin, and effortless tachypnea. *Hypotension is a late finding in shock and indicates significant decompensation has already taken place.* Vascular access is necessary for volume resuscitation in patients with impaired circulation, and an intraosseous line should be considered early on if there is any difficulty in vascular access for a patient requiring resuscitation. Once an intervention is performed, the clinician must reassess the patient.

If the febrile child is older than 3 mo and appears well, if the history or physical examination does not suggest a serious illness, the child may be followed expectantly. This profile applies to most children with acute febrile illnesses. If, on the other hand, the child appears ill, or the history or physical examination suggests a serious infection, definitive laboratory tests appropriate for those findings are indicated (chest x-ray for a child with grunting). If advanced imaging is required (ultrasound or CT scan for suspected appendicitis), it may be prudent to defer such testing to pediatric specialty care if the decision has already been made to transport the child to a higher level of care. The area of greatest controversy is whether laboratory studies are needed in a febrile child who appears well and has no abnormalities on history and physical examination, but who is younger than 3 mo or whose temperature is high. Many would agree that a sepsis work-up is indicated in the febrile child younger than 1 mo and possibly in the febrile child who is as old as 3 mo.

DISPOSITION

The majority of children evaluated in the office for an acute illness can be managed on an outpatient basis. These patients should have reassuring physical examinations, stable vital signs, and adequate follow-up. A mildly dehydrated patient can be discharged to home for a trial of oral rehydration. Patients with a respiratory illness who are exhibiting signs of mild respiratory distress may be monitored at home with a repeat examination scheduled for the next day. Depending on the child's status, the comfort of the parents, and the relationship of the family with the physician, telephone follow-up may be all that is necessary.

If the physician feels comfortable in following as an outpatient the child in whom no specific diagnosis has been established, a follow-up examination may yield the diagnosis. During the initial visit, or from one visit to the next during the acute illness, the change in symptoms or in the findings on physical examination over time may provide important diagnostic clues. For the child in whom a diagnosis has already been established and who does not require hospitalization, follow-up by telephone or an office visit should be used to monitor the course of the illness and to further educate and support the parents.

However, if it is deemed that the child needs a higher level of care, it is the pediatrician's responsibility to decide what method of transfer is appropriate. Physicians may be reluctant to call for help because of a misperception that 911 services should be activated only for full-blown resuscitations. Emergency Medical Services (EMS) transport should be initiated for any child who is physiologically unstable (e.g., with severe respiratory distress, hypoxia, signs of shock, or altered mental status). If the family's ability to comply promptly with

recommendation for emergency department evaluation is in question, that patient should also be transported by EMS. Some physicians and families may defer calling EMS because of the perception that a parent can get to the hospital faster by private car. Although rapidity of transport should be considered, the need for further interventions during transport and the risk of clinical decompensation are other important factors in the decision to activate EMS. Ultimately, the legal responsibility for choosing an appropriate level of transport for a patient lies with the referring physician, until responsibility of care is officially transferred to another medical provider.

Chapter 66

Emergency Medical Services for Children

Joseph L. Wright and Steven E. Krug

The overwhelming majority of the 30 million children who present annually for emergency care in the United States are seen at community hospital emergency departments (EDs). Visits to children's hospital EDs account for just 11% of initial emergency care encounters. This distribution suggests that the greatest opportunity to optimize care for acutely ill or injured pediatric patients, on a population basis, occurs broadly as part of a systems-based approach to emergency services, an approach that incorporates the unique needs of children at every level. Conceptually, emergency medical services for children are characterized by an integrated, continuum of care model (Fig. 66-1). The model is designed such that patient care flows seamlessly from the primary care medical home through transport and on to hospital-based definitive care. It includes the following 5 principal domains of activity:

1. Prevention, primary and secondary
2. Out-of-hospital care, both emergency response and prehospital transport
3. Hospital-based care: ED and inpatient
4. Interfacility transport, as necessary, for definitive or subspecialty care (see Chapter 66.1)
5. Rehabilitation.

Figure 66-1 **The emergency medical services for children (EMSC) continuum of care.** Seriously ill and injured children interface with a large number of healthcare personnel as they move through the EMSC system.

The federal Emergency Medical Services for Children (EMSC) program of the Health Resources and Services Administration's Maternal and Child Health Bureau has stewarded improvements in the care of children in the context of the continuum of care model. The programmatic mission of the EMSC program is as follows:

- To ensure state-of-the-art emergency medical care for the ill or injured child and adolescent.
- To ensure that pediatric services are well integrated into an emergency medical services system and backed by optimal resources.
- To ensure that the entire spectrum of emergency services—including primary prevention of illness and injury, acute care, and rehabilitation—is provided to infants, children, adolescents, and young adults.

EMSC funding to states and U.S. territories has created a national framework upon which necessary advances in education, advocacy, and research are taking place. EMSC grantees, constituents, and stakeholders as well as professional organizations such as the American Academy of Pediatrics are collaboratively engaged in implementation activities and projects that address the pediatric-specific recommendations stemming from the Institute of Medicine (IOM) report *The Future of Emergency Care in the United States Health System*.

THE PRIMARY CARE PHYSICIAN AND OFFICE PREPAREDNESS

The primary care physician (PCP) has multiple important roles in the emergency medical services system. Through anticipatory guidance, the PCP can help shape the attitudes, knowledge, and behaviors of parent and child, with the primary goal of preventing acute medical events, such as injury and status asthmaticus. The point of care initiation for many acute problems is often the PCP office. From the standpoint of personnel, equipment, training, and protocols, the PCP office setting must be adequately prepared to initially manage acute and emergency exacerbations of common pediatric conditions, such as respiratory distress and seizures. Furthermore, on rare occasion, the PCP office environment may be confronted with a child in clinical extremis who requires resuscitative intervention and stabilization. It is, therefore, incumbent upon the PCP not only to ensure access to emergency medical services (EMS), that is, 911 system activation, but also to ensure that there is adequate, onsite psychomotor skill preparation to deal with such an emergency. Office preparedness requires training and continuing education for staff members, protocols for emergency intervention, ready availability of appropriate resuscitation drugs and equipment, and knowledge of local EMS resources and ED capabilities.

Staff Training and Continuing Education

It is a reasonable expectation that all office staff, including receptionists and medical assistants, be trained in cardiopulmonary resuscitation (CPR) and that their certification be maintained on an annual basis. Nurses and physicians should also have training in a systematic approach to pediatric resuscitation. Core knowledge may be obtained through standardized courses in advanced life support (ALS) offered by national medical associations and professional organizations. Frequent recertification is important for knowledge retention and skill maintenance. Examples are the Pediatric Advanced Life Support (PALS) and Pediatric Emergency Assessment, Recognition and Stabilization (PEARS) courses sponsored by the American Heart Association, the Advanced Pediatric Life Support (APLS) course sponsored by the American Academy of Pediatrics (AAP) and the American

College of Emergency Physicians (ACEP), and the Emergency Nurses Pediatric Course (ENPC) sponsored by the Emergency Nurses Association (ENA).

Protocols

Standardized protocols for telephone triage of seriously ill or injured children are essential. When a child's status is in question and prehospital care is available, ambulance transport in the care of trained personnel is always preferable to transport by privately owned vehicle. This obviates the potentially serious medical consequences of relying on unskilled and distraught parents without the ability to provide even basic life support (BLS) measures to an unstable child during transport to an ED. Practitioners can work with their local pediatric emergency care resource center (e.g., children's hospital or academic department of pediatrics) to develop and maintain written protocols for office-based management of a range of conditions, including anaphylaxis, cardiopulmonary arrest, head trauma, ingestions, shock, status asthmaticus, status epilepticus, and upper airway obstruction. Regular practice using mock code scenarios improves office-based practitioner confidence and self-efficacy in managing these problems.

Resuscitation Equipment

Availability of necessary equipment is a vital part of an emergency response. Every physician's office should have essential resuscitation equipment and medications packaged in a pediatric resuscitation cart or kit (Table 66-1). This cart or kit should be checked on a regular basis and kept in an accessible location known to all office staff. Outdated medications, a laryngoscope with a failed light source, or an empty oxygen tank represents a potential catastrophe in a resuscitation scenario. Such an incident can be easily avoided if an equipment checklist and maintenance schedule are implemented. A pediatric kit that includes posters, laminated cards, or a color-coded length-based resuscitation tape specifying emergency drug doses and equipment size is invaluable in avoiding critical therapeutic errors during resuscitation.

To facilitate emergency response when a child needs rapid intervention in the office, all personnel should have designated roles. Organizing a "code team" within the office ensures that necessary equipment is made available to the physician in charge, that an appropriate medical record detailing all interventions and the child's response is generated, and that the 911 call for EMS response or a transport team is made in a timely fashion.

Transport

Once the child has been stabilized, a decision must be made on how to transport a child to a facility capable of providing definitive care. If a child has required airway or cardiovascular support, has altered mental status or unstable vital signs, or has significant potential to deteriorate en route, it is not appropriate to send the child via privately owned vehicle, regardless of proximity to a hospital. Even when an ambulance is called, it is the PCP's responsibility to initiate essential life support measures and to attempt to stabilize the child before transport.

In metropolitan centers with numerous public and private ambulance agencies, the PCP must be knowledgeable about the level of service that is provided by each. The availability of BLS versus ALS services, the configuration of the transport team, and pediatric expertise vary markedly among agencies and across jurisdictions. BLS services provide basic support of airway, breathing, and circulation, whereas ALS units are capable of providing resuscitation drugs and procedural interventions as well. Some communities may have only BLS services available, whereas others may have a 2-tiered system, providing both BLS and ALS. It may be appropriate to consider medical air transport when definitive or specialized care is not available within an immediate community or when ground transport times are prolonged. In that case, initial transport via ground to an appropriate helicopter landing zone or a local hospital for interval stabilization may be undertaken, pending arrival of the air transport team. Independent of whether a child is to be transported by air or ground, copies of the pertinent medical records and any radiologic studies or laboratory results should be sent with the patient, and a call made to the physicians at the receiving facility to alert them to the referral and any treatments administered. Such notification is not merely a courtesy; direct physician-to-physician communication is essential to ensure adequate transmission of patient care information, to allow

Table 66-1 Recommended Drugs and Equipment for Pediatric Office Emergencies

	PRIORITY
DRUGS	
Oxygen	E
Albuterol for inhalation	E
Epinephrine (1 : 1,000)	E
Activated charcoal	S
Antibiotics	S
Anticonvulsants (diazepam/lorazepam)	S
Corticosteroids (parenteral/oral)	S
Dextrose (25%)	S
Diphenhydramine (parenteral, 50 mg/mL)	S
Epinephrine (1 : 10,000)	S
Atropine sulfate (0.1 mg/mL)	S
Naloxone (0.4 mg/mL)	S
Sodium bicarbonate (4.2%)	S
INTRAVENOUS FLUIDS	
Normal saline (NS) or lactated Ringer solution (500-mL bags)	S
5% dextrose, 0.45 NS (500-mL bags)	S
EQUIPMENT FOR AIRWAY MANAGEMENT	
Oxygen and delivery system	E
Bag-valve-mask (450-mL and 1,000-mL)	E
Clear oxygen masks, breather and non-rebreather, with reservoirs (infant, child, adult)	E
Suction device, tonsil tip, bulb syringe	E
Nebulizer (or metered-dose inhaler with spacer/mask)	E
Oropharyngeal airways (sizes 00-5)	E
Pulse oximeter	E
Nasopharyngeal airways (sizes 12-30F)	S
Magill forceps (pediatric, adult)	S
Suction catheters (sizes 5-16F and Yankauer suction tip)	S
Nasogastric tubes (sizes 6-14F)	S
Laryngoscope handle (pediatric, adult) with extra batteries, bulbs	S
Laryngoscope blades (straight 0-2; curved 2-3)	S
Endotracheal tubes (uncuffed 2.5-5.5; cuffed 6.0-8.0)	S
Stylets (pediatric, adult)	S
Esophageal intubation detector or end-tidal carbon dioxide detector	S
EQUIPMENT FOR VASCULAR ACCESS AND FLUID MANAGEMENT	
Butterfly needles (19-25 gauge)	S
Catheter-over-needle device (14-24 gauge)	S
Arm boards, tape, tourniquet	S
Intraosseous needles (16-, 18-gauge)	S
Intravenous tubing, micro-drip	S
MISCELLANEOUS EQUIPMENT AND SUPPLIES	
Color-coded tape or preprinted drug doses	E
Cardiac arrest board/backboard	E
Sphygmomanometer (infant, child, adult, thigh cuffs)	E
Splints, sterile dressings	E
Automated external defibrillator with pediatric capabilities	S
Spot glucose test	S
Stiff neck collars (small/large)	S
Heating source (overhead warmer/infrared lamp)	S

E, essential; S, strongly suggested.

From American Academy of Pediatrics, Committee on Pediatric Emergency Medicine; Frush K: Policy statement-preparation for emergencies in the offices of pediatricians and pediatric primary care providers, Pediatrics *120:200-212, 2007. Reaffirmed* Pediatrics *128:e748, 2011.*

mobilization of necessary resources in the ED, and to redirect the transport if the emergency physician believes that the child would be more optimally treated at a facility with specialized services.

PEDIATRIC PREHOSPITAL CARE

Prehospital care refers to emergency assistance rendered by trained emergency medical personnel before a child reaches a treating medical facility. The goals of prehospital care are to further minimize systemic insult or injury through a series of well-defined and appropriate interventions and to embrace principles that ensure patient safety. Most communities in the United States have a formalized EMS system; the organizational structure and nature of emergency medical response depend greatly on local demographics and population base. EMS may be provided by volunteers or career professionals working in a fire-based or independent “third service” response system. Key points to recognize in negotiation of the juncture between the community physician and the local EMS system include access to the system, provider capability, and destination determination.

Access to the EMS System

Virtually all Americans have access to the 911 telephone service that provides direct access to a dispatcher who coordinates police, fire, and EMS responses. Some communities have an enhanced 911 system, in which the location of the caller is automatically provided to the dispatcher, permitting emergency response even if the caller, such as a young child, cannot give an address. The extent of medical training for these dispatchers varies among communities, as do the protocols by which they assign an emergency response level (BLS vs ALS). In some smaller communities, no coordinated dispatch exists, and emergency medical calls are handled by the local law enforcement agency.

When activating the 911 system, the physician must make clear to the dispatcher the nature of the medical emergency and the condition of the child. In many communities, emergency medical dispatchers are trained to ask a series of questions per protocol that determines the appropriate level of provider to be sent.

Provider Capability

There are many levels of training for prehospital EMS providers, ranging from individuals capable of providing only first aid to those trained and licensed to provide ALS. All EMS personnel, whether basic emergency medical technicians (EMTs) or paramedics, receive training in pediatric emergencies; however, pediatric cases actually constitute roughly 10% of all EMS transports.

First responders may be law enforcement officers or firefighters, who are dispatched to provide emergency medical assistance, or bystanders. Public safety personnel have a minimum of 40 hr of training in first aid and CPR. Their role is to provide rapid response and stabilization pending the arrival of more highly trained personnel. In some smaller communities, this may be the only prehospital emergency medical response available.

In the United States, the bulk of emergency medical response is provided by EMTs, who may be volunteers or paid professionals. Basic EMTs may staff an ambulance after undergoing a training program of approximately 100 hr. They are licensed to provide BLS services but may receive further training in some jurisdictions to expand their scope of practice to include intravenous catheter placement and fluid administration, management of airway adjuncts, and the use of an automated external defibrillator.

Paramedics, or EMT-Ps, represent the highest level of EMT response, with medical training and supervised field experience of approximately 1,000 hr. Paramedic skills include advanced airway management, including endotracheal intubation; placement of peripheral, central, or intraosseous lines; intravenous administration of drugs; administration of nebulized aerosols; needle thoracostomy; and cardioversion and defibrillation. These professionals provide ALS services, functioning out of an ambulance equipped as a mobile intensive care unit. In a joint policy statement entitled *Equipment for Ground Ambulances*, the AAP, the ACEP, the American College of Surgeons Committee on Trauma, EMSC, the ENA, the National Association of EMS Physicians, and the National Association of EMS Officials have published guideline standards for essential ambulance equipment, medications, and supplies necessary to provide BLS and ALS care across the age spectrum. This essential equipment list represents one of the reference standards that the federal EMSC program has adopted as a performance measure for state-level operational readiness to care for children in an EMS system.

Both basic EMTs and paramedics function under the delegated licensing authority of a supervisory EMS medical director. This physician oversight of prehospital practice is broadly characterized under the umbrella term *medical control*. **Direct, or online, medical control** refers to medical direction either at the scene or in real time via voice or video transmission. **Indirect, or offline, medical control** refers to the administering of medical direction prior to and after the provision of care. Offline activities, such as provider education and training, protocol development, and medical leadership of quality assurance/quality improvement programs, represent areas in need of greater pediatric input. As a measure of the degree to which EMSC permanence is being established in state EMS systems, the federal EMSC program has required demonstration of participation in online and offline medical direction activities for pediatric patients and the seating of an EMSC advisory committee at the state level. These advisory bodies are well positioned to support EMS agencies in their pediatric readiness as well as provide a forum for the active engagement of pediatric care experts at a system level.

Destination Determination

The destination to which a pediatric patient is transported may be defined by parental preference, provider preference, or jurisdictional protocol, which is typically predicated on field assessment of anatomic and physiologic criteria and, in the case of trauma, mechanism of injury. In communities served by an organized trauma or regionalized EMS system that incorporates pediatric designation based on objectively verified hospital capabilities, seriously ill or injured children may be triaged by protocol to the highest-level center reachable within a reasonable amount of time. The mantra is to deliver the child to the **“right care in the right time,”** even if it requires bypassing closer hospitals. An exception is the child in full arrest, for whom expeditious transport to the nearest facility is always warranted. In 2012, modification of the Centers for Disease Control and Prevention’s national field trauma triage guidelines included a refinement of age-specific vital sign assessment criteria to more accurately reflect the unique physiologic response to injury in children. The Centers for Disease Control and Prevention guidelines are a valuable resource for pediatricians involved in EMS medical direction and are accessible as a multipurpose toolkit, including an educational webinar and downloadable mobile application, at http://www.cdc.gov/fieldtriage.

Regionalization in the context of EMS is defined as a geographically organized system of services that ensures access to care at a level appropriate to patient needs while maintaining efficient use of available resources. This system concept is especially germane in the care of children, given the relative scarcity of facilities capable of managing the full range and scope of pediatric conditions (Fig. 66-2). Regionalized systems of care coordinated with emergency medical dispatch, field triage, and EMS transport have demonstrated efficacy in improving outcomes for pediatric trauma patients, especially for younger children and for children with isolated head injury. Emerging evidence also suggests a similar benefit conferred to children in shock identified in the field who are preferentially transported to hospital EDs with documented pediatric ALS capability. The existence of statewide or regional standardized systems that formally recognize hospitals able to stabilize and/or manage pediatric medical emergencies is another federal EMSC performance measure against which operational capacity to provide optimal pediatric emergency care in this country is currently being judged.

In communities that do not have a hospital with the equipment and personnel resources to provide definitive pediatric inpatient care, interfacility transport of a child to a regional center should be undertaken after initial stabilization (see Chapter 66.1). When interfacility

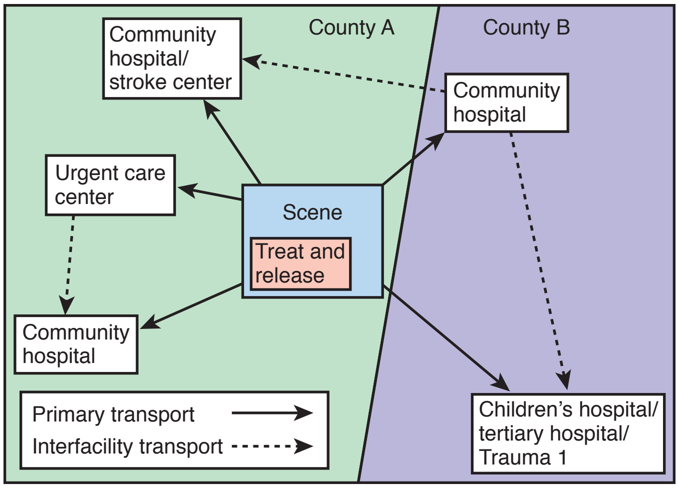

Figure 66-2 Transport options within a coordinated, regionalized emergency medical services system model. The objective is to ensure access to definitive care at a level appropriate to meet patient needs. *Solid arrows,* primary transport; *dotted arrows,* interfacility transport. *(Adapted from Institute of Medicine, Committee on the Future of Emergency Care in the U.S. Health System:* Hospital-based emergency care: at the breaking point, *Washington, DC, 2006, National Academies Press.)*

transport is to be undertaken, indications for transfer, parental consent for transfer, and acceptance of the patient by the receiving physician must all be clearly documented in the medical record.

THE EMERGENCY DEPARTMENT

The ability of hospital EDs to respond to the emergency care of children varies and depends on a number of factors in addition to availability of equipment and supplies. Training, awareness, and experience of the staff as well as access to pediatricians and medical and surgical subspecialists also play a key role. The majority of children who require emergency care are evaluated in community hospitals by physicians, nurses, and other healthcare providers with variable degrees of pediatric training and experience. Although children account for 25-30% of all ED visits, only a fraction of these encounters represent true emergencies. Because the volume of critical pediatric cases is low, emergency physicians and nurses working in community hospitals often have limited opportunity to reinforce their knowledge and skills in the assessment of ill or injured children and in pediatric resuscitation. General pediatricians from the community may be consulted when a seriously ill or injured child presents to the ED, and they should have a structured approach to the initial evaluation and treatment of an unstable child of any age, regardless of the underlying diagnosis. Early recognition of life-threatening abnormalities in oxygenation, ventilation, perfusion, and central nervous system function and rapid intervention to correct those abnormalities are key to successful resuscitation and stabilization of the pediatric patient.

In its report *The Future of Emergency Care in the U.S. Health System*, the IOM strongly recommended that hospitals and EMS systems appoint qualified coordinators for pediatric emergency care, a recommendation consistent with pediatric emergency readiness guidelines advocated by the AAP and ACEP. Only 18% of EDs in the United States currently appoint a physician coordinator, and 12% appoint a nursing coordinator for pediatric emergency care. EDs that do appoint these positions tend to be more prepared as measured by compliance with nationally published guidelines on the care of children in the ED.

Minimum standards must be met by community EDs to ensure that children receive the best emergency care possible. Updated guidelines for the care of children in the ED have been published, reaffirmed and are endorsed by the AAP, the ACEP, and the ENA. These guidelines provide current information on policies, procedures, protocols, quality assurance methods, and equipment and supplies considered essential for managing pediatric emergencies. Specific recommendations on equipment, supplies, and medications for the ED are listed and updates are available on the AAP website. Table 66-2 lists sample policies, procedures, and protocols specifically addressing the needs of children in the ED.

The way in which the family supports the child during a crisis and, consequently, how the family is supported in the ED when caring for the child are critical to patient recovery, family satisfaction, and

Table 66-2 Guidelines for Pediatric-Specific Policies, Procedures, and Protocols for the Emergency Department
Illness and injury triage
Pediatric patient assessment and reassessment
Documentation of pediatric vital signs, abnormal vital signs, and actions to be taken for abnormal vital signs
Immunization assessment and management of the underimmunized patient
Sedation and analgesia for procedures, including medical imaging
Consent (including situations in which a parent is not immediately available)
Social and mental health issues
Physical or chemical restraint of patients
Child maltreatment (physical and sexual abuse, sexual assault, and neglect) mandated reporting criteria, requirements, and processes
Death of the child in the emergency department
Do-not-resuscitate orders
Family-centered care, including: 1. Involving families in patient care decision-making and in medication safety processes. 2. Family presence during all aspects of emergency care, including resuscitation. 3. Education of the patient, family, and regular caregivers. 4. Discharge planning and instruction. 5. Bereavement counseling.
Communication with patient's medical home or primary healthcare provider
Medical imaging policies that address age- or weight-appropriate dosing for children receiving studies that impart ionizing radiation, consistent with ALARA (as low as reasonably achievable) principles
All-hazard disaster preparedness plan that addresses the following pediatric issues: a. Availability of medications, vaccines, equipment, and appropriately trained providers for children in disasters. b. Pediatric surge capacity for both injured and noninjured children. c. Decontamination, isolation, and quarantine of families and children of all ages. d. A plan that minimizes parent-child separation and includes system tracking of pediatric patients, allowing for the timely reunification of separated children with their families. e. Access to specific medical and mental health therapies, as well as social services, for children in the event of a disaster. f. Disaster drills, which should include a pediatric mass casualty incident at least every 2 yr. g. Care of children with special healthcare needs. h. A plan that includes evacuation of pediatric units and pediatric specialty units.

Data from American Academy of Pediatrics Committee on Pediatric Emergency Medicine; American College of Emergency Physicians Pediatric Committee; Emergency Nurses Association Pediatric Committee: Joint policy statement—guidelines for care of children in the emergency department, Pediatrics *124:1233-1243, 2009. Reaffirmed* Pediatrics *132:e281, 2013.*

the mitigation of posttraumatic stress. Commitment to patient- and family-centered care in the ED ensures that the patient and family experience guides the practice of culturally sensitive care and promotes patient dignity, comfort, and autonomy. In the ED setting, particular issues, such as family presence, deserve specific attention. Surveys of parents have indicated that most want to be with their child during invasive procedures and even during resuscitation. Allowing their presence has been shown to reduce parental and patient anxiety and does not interfere with procedure performance. Patient- and family-centered care is also associated with improved care quality and patient safety.

EMERGING ISSUES IN EMSC

Of the pediatric-specific recommendations promulgated by the IOM in its widely publicized 2006 report on the future of emergency care, 3 have emerged as especially important for EMSC. The first deals directly with increased federal funding for the EMSC program, which supports more than 80 grantees with an established presence in 49 states, 5 U.S. territories, the District of Columbia, and the freely associated states of Micronesia, Palau, and the Marshall Islands. The grant awards cover 5 distinct funding categories ranging from basic science and clinical investigation to public sector capacity-building programs to national technical assistance centers to multicenter trials conducted within a large research network. Through the diversity of activity generated within the program, and in collaboration with stakeholders, the EMSC program affords synergistic opportunity to further the progress realized in the program's first 30 yr of existence. A tumultuous appropriations history not-with-standing, including several years of budget elimination, Congressional reauthorization, due in 2014, and will ensure stability for the EMSC program at least in the near term.

In addition to EMSC resource support, the IOM also recommended that (a) federal agencies in partnership with state and regional planning bodies and emergency care provider organizations convene a panel with multidisciplinary expertise to develop strategies for addressing pediatric needs in the event of a disaster, and (b) the U.S. Department of Health and Human Services conduct a study to examine the gaps and opportunities in emergency care research, including pediatric emergency care, and recommend a strategy for the optimal organization and funding of the research effort. Both of these recommendations have generated activity of significant import to the emergency care community, EMSC specifically, and warrant mention.

Disaster Preparedness

Children constitute approximately 30% of the population; in a catastrophic event, natural or human-made, several unique factors place children at disproportionate, increased risk. During the day large groups of children are typically cohorted, separate from their families, in schools and daycare centers where mass casualties can easily occur and reunification is challenging. Furthermore, in the event of a biologic or chemical attack, unique anatomic, developmental, and physiologic features make children especially vulnerable to absorption and/or inhalation of toxic agents. Following the broad pediatric impact of the devastating Gulf Coast hurricanes Katrina and Rita in the mid-2000s, Congress established the National Commission on Children and Disasters. The Commission's mandate was to conduct a comprehensive study to examine and assess the needs of children as they relate to preparation for, mitigation of, response to, and recovery from all hazards, including major disasters and emergencies. The findings and recommendations of the Commission's 2010 report to the President and to Congress have established a broad framework for ongoing preparedness efforts related not only to child physical health, but also, importantly, to behavioral and emotional well-being. In addition, pertinent resources related to pediatric-focused areas of concerns such as evacuation, separation-reunification, sheltering, countermeasures, surge capacity and triage are being monitored and chronicled under the PEDPrepared Disaster Clearinghouse at the EMSC National Resource Center website, http://www.emscnrc.org/pedprepared.

66.1 Interfacility Transport of the Seriously Ill or Injured Pediatric Patient

*Elizabeth A. Edgerton and Bruce L. Klein**

Patients often seek treatment at facilities that lack sufficient expertise to treat their conditions, necessitating transfer to more appropriate specialty centers. This is especially pronounced in pediatrics. EMS providers or parents usually take children to local EDs first, where their conditions and physiologic stabilities are assessed. Although bringing a child directly to the local ED may be proper logistically, local EDs can be less than ideal for pediatric emergencies. Children account for 27% of all ED visits but only 6% of EDs have all the necessary supplies for pediatric emergencies. Also, general EDs are less likely to have pediatric expertise or policies in place for the care of children. Outcomes for critically ill children treated in pediatric intensive care units (PICUs) are better than for those treated in adult ICUs. When pediatric critical care is required, transport to a regional PICU is indicated. In addition, often the type of subspecialty care needed (e.g., pediatric orthopedics) is available only at the pediatric center.

Pediatric transport medicine consists of the interfacility transfer of infants, children, and adolescents from community facilities to pediatric centers that can provide the needed level of expertise. Transport is performed by professionals proficient in pediatric transport on specially age-equipped ground, rotorcraft, or fixed-wing ambulances. Pediatric transport medicine is a multidisciplinary field comprising pediatric critical care and pediatric emergency medicine physicians (and, sometimes for very young infants, neonatologists); nurses, respiratory therapists, and paramedics with advanced training for pediatric transport; and communications specialists. The goal is to deliver quality pediatric care to the region's children, while optimizing the use of regional resources. For the individual child, the aim is to stabilize and, when appropriate, begin treating as soon as possible—that is, at the local ED and during transport, well before arrival at the referral center.

The AAP Section on Transport Medicine, the Association of Air Medical Services, the Federal Aviation Administration (FAA), and others have published recommendations regarding transport programs. Models for pediatric transport services vary depending on the needs and available resources in a geographic region, but all should have certain basic components: a network of community hospitals and regional pediatric centers; an established communications and dispatch system that easily facilitates transfer to the pediatric center; ground and/or air ambulances; medical and nursing leadership from pediatric critical care or pediatric emergency medicine (or neonatology); experienced pediatric medical control physicians (MCPs); a multidisciplinary team of pediatric transport professionals specially trained to provide the appropriate level of care required during transport; operational and clinical policies and procedures that guarantee safe, state-of-the-art, and timely pediatric critical care transport; and a database for quality and performance assessment.

COMMUNICATIONS AND DISPATCH CENTER

Communications are one of the most vital components of a regional transport system. Treating a critically ill or injured child is an uncommon event for most community physicians. Therefore, they need to know *whom*, *how*, and *when* to call for assistance in the stabilization and transfer of a pediatric patient. The communications and dispatch center provides a single telephone number for such calls.

The communications and dispatch center coordinates communications among the outlying facility, receiving unit, MCP, transport team, and others. This center may be part of a hospital unit (e.g., ED, PICU), self-contained in a single institution (e.g., Emergency Communications and Information Center), or based offsite as a freestanding center coordinating communications and dispatch for multiple transport programs.

Staffing varies depending on the type of center. On-duty nurses or physicians may receive calls at unit-based models with low volumes.

*Adapted initially from Dr. Lorry R. Frankel's chapter in the 18th edition of this book.

In contrast, dedicated communications specialists usually staff self-contained or freestanding centers, which tend to be busier. The communications specialist has numerous responsibilities, including answering the referring physician's call promptly; documenting essential patient demographic information; arranging for immediate consultation with the MCP; dispatching the transport team to the referring facility expeditiously; updating the referring facility with any changes in the arrival time; and coordinating medical control and other necessary transport-related calls. The transport team must be equipped with a cellular telephone or radio for immediate contact with the receiving and referring facilities.

MEDICAL CONTROL PHYSICIAN

The MCP is involved in the clinical care and safe transport of the patient from the time of referral through arrival at the receiving hospital unit. The MCP's oversight increases once the transport team arrives at the referring facility. The MCP should have expertise in pediatric critical care or pediatric emergency medicine (or sometimes neonatology). Besides having the knowledge required to stabilize a critically ill or injured child, the MCP must be familiar with the transport environment; the transport team members' capabilities; the program's policies and procedures; and the region's geography, medical resources, and regulations regarding interhospital transport. The MCP must possess good interpersonal and communication skills and must be able to maintain collegiality with the referring hospital's staff during a potentially difficult and stressful situation.

Once a transport call is received, the MCP must be immediately available to confer with the referring physician. Although the MCP may have other responsibilities, these transport responsibilities take priority in order to avoid undue delays when transferring a critically ill child. Often the MCP recommends further testing or therapeutic interventions that can be delivered by the referring hospital before the transport team arrives. The MCP may seek additional guidance from other specialists, as necessary. Because the child's condition may change rapidly, the MCP must remain ready to give additional advice. All conversations and recommendations regarding the care of the patient should be documented. Some centers record these conversations.

After discussion with the referring physician—and, when warranted, with the transport staff—the MCP determines the best team composition and vehicle for transport. The MCP usually does not accompany the team but remains available, by phone or radio, to supervise care.

TRANSPORT TEAM

Transport team composition varies among programs—and sometimes within an individual program. The team's composition is based on a variety of factors, including the severity of the child's illness or injury; the distance to the referring facility; the team members' advanced practice abilities; the referrer's (reasonable or unreasonable) insistence that a physician be present; the program's historical professional makeup; and the region's staffing regulations. The team should be composed of physicians, nurses, respiratory therapists, and/or paramedics who have expertise in pediatric critical care or pediatric emergency medicine (or neonatology in some cases), as well as advanced education and training in those cognitive and procedural areas important for pediatric critical care transport. There is a lower incidence of transport-related morbidity for critically ill and injured children transported by pediatric specialty teams than for those transported by generalist teams.

Various scoring systems have been developed to predict the need for a physician during transport. It seems that a team member's training, experience, and skill in treating critically ill patients are more important considerations than that team member's professional degree. Team members must understand basic pediatric pathophysiology and collectively must be able to assess and monitor a critically ill or injured child; manage the airway and provide respiratory support; obtain vascular access; perform point-of-care testing; and administer those medications commonly used in pediatric critical care transport. They must be familiar with the physiologic alterations as well as practical difficulties of the transport environment and, importantly, must be comfortable working in an out-of-hospital setting. Physicians are less often deployed on transport teams in part because of the advanced training that other healthcare professionals on the transport team receive.

The transport team should have a designated team leader who, in addition to the team leader's many other responsibilities, interacts with the MCP during the transport. Once the team arrives at the referring facility, the team should reassess the child's condition, review all of the pertinent diagnostic studies and therapies, and discuss the situation with the referring staff and parents. If the patient's condition has changed significantly, the team leader may need to contact the MCP for additional advice. Otherwise, the team leader should generally notify the MCP before starting to bring the child to the receiving facility. Any care delivered by the team during transport should be documented, and copies of all medical records—including laboratory data, radiographs, and scans—should accompany the child to the pediatric center. The receiving unit must be updated prior to arrival so it can finalize preparations for the patient.

GROUND VERSUS AIR AMBULANCE

Transport options include ground, rotorcraft, and fixed-wing ambulances. Vehicle selection depends on the child's emergency needs; transport team's capabilities; any out-of-ordinary staffing or equipment requirements (e.g., for extracorporeal membrane oxygenation, inhaled nitric oxide or heliox); referring facility's abilities; distance; terrain; traffic patterns; ground or air ambulance availability; helicopter landing pad or airport access; weather conditions; and expense.

The transport vehicle must be equipped with electrical power, oxygen, and suction and must have sufficient space for the equipment and supplies that the team brings along—stretcher or isolette, monitor, ventilator, oxygen tank(s), medication pack(s), infusion pumps, and more. Compared with helicopters, ambulances are more spacious and able to carry more weight, so they can accommodate larger teams and more equipment. Another advantage of ground ambulance transport is the ability to stop en route if the patient's condition deteriorates; this feature greatly facilitates the performance of certain interventions, such as intubation.

An airplane may be able to fly to an area when distance (>150 miles), altitude, or weather precludes helicopter use. However, the use of an airplane necessitates several ambulance transfers, with their attendant delays and potential complications. There also are delays when the plane must fly from a remote base to the program's jurisdiction.

TRANSPORT PHYSIOLOGY

When possible, the transport team tries to provide the same care during transport as the patient would receive in the specialty center. This can be difficult, though, because of limitations in personnel, equipment, and space, as well as other environmental challenges.

The team and child are subjected to variable intensities of background noise and vibration while traveling in the vehicle cabin. Noise can impair the team's ability to auscultate breath sounds, heart sounds, and blood pressure, another reason for monitoring vital signs mechanically and relying on other assessment modalities, such as the level of mentation, skin color, and capillary refill. To mitigate noise, the helicopter crew and patient should wear helmets or headphones (or another wearable noise attenuator such as MiniMuffs [Natus Medical Incorporated, San Carlos, CA]). Motion and vibration can lead to increased metabolic rate, shortness of breath, and fatigue in the patient, as well as motion sickness in the patient and staff.

On fixed- or certain rotary-wing transports, the patient may suffer adverse physiologic effects from altitude. With increasing altitude, the barometric (atmospheric) pressure decreases and gases expand. As the barometric pressure drops and gas expands, the partial pressures of ambient oxygen (PO_2) and, consequently, arterial oxygen (PaO_2) decrease. For example, at 8,000 feet—an elevation at which unpressurized airplanes may fly, as well as the effective cabin altitude for many pressurized airplanes flying at 35,000 to 40,000 feet—the barometric pressure, PO_2, PaO_2, and arterial oxygen saturation fall to 565 mm Hg, 118 mm Hg, 61 mm Hg, and 93%, respectively. (In comparison, the barometric pressure, PO_2, PaO_2, and arterial oxygen saturation are

760 mm Hg, 159 mm Hg, 95 mm Hg, and 100% at sea level.) Although healthy individuals usually tolerate these changes well, patients with respiratory insufficiency, significant blood loss, or shock may decompensate and should receive supplemental oxygen.

Gases expand 10-15% at the few thousand feet at which helicopters typically fly, and approximately 30% at 8,000 feet. Gases within the body itself also expand as the altitude increases. Gas expansion must be appreciated during transport via air of a patient with a pneumocephalus, pneumothorax, bowel obstruction, or another condition involving entrapped gas. Prior to transport, a pneumothorax should be decompressed, and a nasogastric tube inserted for ileus.

SAFETY

Safety is of paramount importance and mandates constant vigilance by everyone involved. Accident rates for pediatric air and ground transport are estimated at approximately 1/1,000 transports. The team should routinely attend pilot briefs, as well as perform safety inspections of the vehicles and equipment, aided by checklists. When in doubt, the MCP should solicit input from the staff about whether to transport via air or ground ambulance or to employ lights and sirens, decisions that cannot be taken lightly. The pilot's or driver's judgment as to the safety of proceeding during inclement weather or with a mechanical problem must not be overruled.

Organizations, such as the FAA and the National Transportation Safety Board, play a role in ensuring safe interfacility transport. The Commission on Accreditation of Medical Transport Systems (CAMTS) is an independent, peer review organization that was established in 1990 in response to the number of air medical accidents in the 1980s. CAMTS, through voluntary participation, audits and accredits fixed-wing, rotary-wing, and ground interfacility medical transport services.

FAMILY-CENTERED CARE

Family-centered care represents a philosophy that respects the important role that family members play in a child's care. It recognizes family members and healthcare providers as partners in caring for the child. Family presence during transport is beneficial because it provides support to children in stressful situations and assists healthcare providers in delivering care to patients with complex and/or chronic medical problems.

As care is transitioned from the referring hospital, it is the transport team's responsibility to maintain family-centered care. The team meets with family members to explain the transport process, obtain consent, and discuss anticipated management. When possible, the transport team should attempt to accommodate a family member's presence onboard. However, the family member and child may need to be separated when the child is critically ill and rapid transport is essential, or if there is space or weight limitations in the air or ground ambulance. In these situations, it is important that family members have a clear understanding of how the child will be cared for during the separation.

REFERRING HOSPITAL RESPONSIBILITIES

Transfer of a patient to another facility requires written documentation by the referring physician of the need and reasons for transfer, including a statement that the risks and benefits, as well as any alternatives, have been discussed with the parents. The parent's informed consent to the transfer should be obtained.

Federal law under the Emergency Medical Treatment and Active Labor Act (EMTALA), part of the Consolidated Omnibus Budget Reconciliation Act (COBRA), imposes specific requirements that a patient presenting to an ED be given a medical screening examination without regard to ability to pay. If upon examination an emergency medical condition is found, the hospital is required to stabilize the patient or to transfer the patient to another facility if unable to stabilize the patient or if requested by the patient. The primary requirement is that the referring physician must certify that the medical risks of transfer are outweighed by its potential benefits. The receiving hospital must agree to accept the patient and have the space and staff to provide the necessary treatment. The transferring hospital is responsible for arranging for the transfer and ensuring that it is performed by qualified medical personnel with appropriate equipment. It must send copies of the patient's medical records and test results, even those that become available after the transfer is complete.

Some referring hospitals have entered into transfer agreements with specialty centers in the interests of facilitating the smooth and safe transfer of the pediatric patient. Having prepared forms for all of the above purposes also aids in the transfer process.

Each hospital needs to review its facility's guidelines, and if established guidelines do not exist the EMSC, in partnership with the Emergency Nurses Association and the Society of Trauma Nurses, has developed the "Inter Facility Transfer Tool Kit for the Pediatric Patient" (available at www.pediatricreadiness.org). This tool kit includes the essentials for comprehensively and safely transferring the pediatric patient to the most appropriate level of care in a timely manner.

EDUCATIONAL OUTREACH

Besides safe and rapid transport, regional pediatric transport programs (and their specialty centers) have an obligation to provide educational opportunities to community healthcare providers so that these providers can acquire the necessary skills to evaluate and stabilize a critically ill or injured child until the transport team arrives. These learning activities may include transport case reviews; lectures on pediatric acute care topics; resuscitation programs such as the PALS course, APLS course, and S.T.A.B.L.E. (sugar and safe care, temperature, airway, blood pressure, lab work, emotional support) program; and rotations through the specialty center's pediatric ED and PICU. These activities also help cement relationships with the referring facility's staff.

66.2 Outcomes and Risk Adjustment

Evaline A. Alessandrini

Health services research has documented wide variation in the likelihood that patients receive quality, evidence-based healthcare, and this can negatively impact the health of children and youth. The complexities of delivering high-quality healthcare are magnified in the ED. Patients are in crisis, EDs are often overcrowded, patient–physician relationships are based on brief interactions, and the variety of complaints and diagnoses is immense.

OUTCOME MEASURES IN EMERGENCY MEDICAL SERVICES FOR CHILDREN

Emergency Care for Children: Growing Pains, one report of the 2007 IOM series on the future of emergency care, recommends that pediatric emergency medical systems specifically support the development of national standards for emergency care performance measurement. The Donabedian structure–process–outcome model has set the framework for most contemporary quality measurement and improvement activities. Structural elements provide indirect quality-of-care measures related to a physical setting and resources. Process indicators provide a measure of the quality of care and services by evaluating the method or process by which care is delivered, including both technical and interpersonal components. Outcome elements describe valued results related to lengthening life, relieving pain, reducing disabilities, and satisfying the consumer.

Defining relevant outcomes for pediatric emergency care is difficult. A true "outcome-based" approach describes observable measures such as mortality, risk of organ system failure, and disability. An alternative approach is a "resource-based" outcome measure definition related to the level of care required. Children who are more ill, in general, require more resources. Thus, resource use across groups of patients reflects relative severity of illness in the groups. Examples of resource-based outcomes include need for hospital admission (ED disposition), ED

Table 66-3	Stakeholder-Endorsed Outcome Measures for Pediatric Emergency Care

- Overall patient satisfaction with ED visit—nurses
- Overall patient satisfaction with ED visit—physicians
- Parent/caregiver understanding of ED discharge instructions
- ED length of stay for patients <18 yr of age
- Percentage of patients <18 yr of age left without being seen (LWBS)
- Effective pediatric procedural sedation
- Acute fracture patients with documented reduction in pain within 90 min of ED arrival
- Improvement in asthma severity score for patients with acute exacerbations
- ED revisit within 48 hr resulting in admission
- Medication error rates
- Global sentinel never events
- Unplanned return visit within 72 hr for the same/related asthma exacerbation
- Failure to achieve seizure control within 30 min of ED arrival
- Return visits within 48 hr resulting in admission for all urgent and emergency patients

Table 66-4	Elements of the PRISA II Score

- Age <90 days
- Minor injury
- Abdominal pain in an adolescent
- Immunodeficiency
- Indwelling medical device
- Controller asthma medication
- Referral status
- Temperature
- Decreased mental status
- Low systolic blood pressure (<70 neonates and infants; <83 children; <100 adolescents)
- High diastolic blood pressure (>59 neonates and infants; >70 children; >90 adolescents)
- Low serum bicarbonate value (<20 mEq/L)
- High potassium value (>4.9 mEq/L)
- High blood urea nitrogen value (>80 mg/dL)
- High white blood cell count (>20,000/mm^3)
- Oxygen therapy other than during inhaled bronchodilator treatments
- Low bicarbonate and high potassium values

Table 66-5	Elements of the RePEAT Score

- Age
- Chief complaint
- Triage category
- Current use of prescription medications
- Arrival via EMS (ground/air)
- Heart rate
- Respiratory rate
- Temperature

length of stay, costs, and diagnostic and therapeutic interventions performed in the ED. Table 66-3 provides a list of outcome measures for pediatric emergency care developed by EMSC stakeholders during 2 separate consensus meetings.

RISK ADJUSTMENT

Measuring outcomes offers opportunities for EDs and other components of the healthcare system to make effective improvements over time, benchmark, and compare their end results with those of other institutions. Meaningful comparisons between EDs or within an ED over time generally require risk adjustment, which accounts for patient-related attributes such as age, or for preexisting conditions associated with the outcome of interest. Risk-adjustment "levels the playing field," so that comparison of outcomes is as fair and meaningful as possible. Because children present to EDs with illnesses of varying acuity, ranging from rashes and colds to cardiac arrest, there is an inextricable linkage of severity to outcomes. Severity typifies the concept of "risk"—the higher the severity, the higher the risk of a given outcome. Without risk adjustment, EDs with sicker patients may appear to have worse outcomes.

A large number of instruments have been developed to adjust for severity or risk in clinical research and quality improvement activities. The commonly used PRISM (Pediatric Risk of Mortality) score is not well-suited for EMSC, given the extremely low rate of mortality. Several disease-specific acuity scoring systems are available for use in EMSC. The majority of these are intended for use in trauma patients, including the Injury Severity Score, Trauma Score, and Pediatric Trauma Score.

RISK ADJUSTMENT TOOLS IN EMSC

The choice of a risk-adjustment tool depends on several factors, including the population under study, the setting, and the outcomes of interest. Two risk-adjustment tools have been developed specifically for pediatric emergency medicine, the second-generation Pediatric Risk of Admission (PRISA II) score and the Revised Pediatric Emergency Assessment Tool (RePEAT).

Pediatric Risk of Admission II

PRISA II uses components of acute and chronic medical history and physiology to determine the probability of hospitalization. The outcome measure of interest is mandatory hospital admission (admissions utilizing therapies best delivered on an inpatient basis). Table 66-4 lists the patient-related attributes contributing to the PRISA II risk-adjustment score. Analytic models including the PRISA II score have good calibration (how well the probabilities predicted from the model correlated with the observed outcomes in the population) and discrimination (the ability to categorize subjects correctly into the categories of interest) with respect to mandatory hospital admission. Construct validity of the PRISA score was demonstrated by measuring the rates of the secondary outcomes: mandatory admission, PICU admission, and mortality. As the probability of hospital admission rose, the proportion of patients with these increasing care requirements also increased. This finding strongly supports the use of the PRISA II score as a valid measure of severity of illness. In addition, PRISA II was used to demonstrate racial/ethnic differences in severity-adjusted hospitalization rates, and also demonstrated that teaching hospitals had higher than expected severity-adjusted admission rates in comparison with nonteaching hospitals.

Revised Pediatric Emergency Assessment Tool

The RePEAT uses a limited set of data collected at the time of triage to model severity of illness as reflected by the level of care provided in the ED. This tool was developed to predict the level of care provided—routine assessment (clinical examination only ± nonprescription medicine), specific ED care (ED diagnostics and/or therapeutics), or hospital admission—with the implicit assumption that patients with a higher level of care have a higher severity of illness. Table 66-5 lists the patient-related attributes contributing to the RePEAT risk-adjustment score. As with the PRISA II score, analytic models including the RePEAT score have good calibration and discrimination with respect to predicting ED care and hospital admission. Furthermore, analytic models that compare costs and ED length of stay between EDs are improved by adjustment for severity of illness using the RePEAT score. These results demonstrate that RePEAT is a reasonable marker of severity of illness and that inclusion of this severity index substantially improves the ability to compare outcomes between EDs.

66.3 Principles Applicable to the Developing World

Jennifer I. Chapman and David M. Walker

International pediatric emergency medicine is an emerging academic field whose practitioners are committed to international collaboration aimed at improving the quality of care for children outside their national borders (Table 66-6).

Many models currently exist for the delivery of emergency care. The **triage officer** model is one in which a practitioner who works in an ED briefly provides intake for all patients and calls specialists to provide definitive care depending on the nature of the presenting complaint. The **multiple physician** model describes a scenario in which patients are divided by their chief complaints into medical, surgical, and pediatric groups. The field of emergency medicine provides a specialist skilled in the recognition, stabilization, and definitive treatment of a wide variety of acute illnesses and injuries. This approach to managing an emergency center is more efficient, relies less heavily on specialist availability, and requires fewer highly trained practitioners to operate. Children and adolescents constitute a subpopulation of emergency patients that deserves special attention because of pediatric-specific conditions, unique anatomy and physiology, developmental staging, and parental interactions.

The maturity of pediatric emergency medicine (PEM) in any given area depends on the healthcare priorities and resources of that geographic or physical setting. The places in which emergency care takes place range from the community (for those with no access to organized medical care) to state-of-the-art pediatric EDs in populated centers. The scope ranges from care of the individual patient to the management of populations of children involved in large-scale disasters. Barriers to quality care are different in each situation and in each part of the world, with the implication for the astute international PEM practitioner that solutions must be targeted to the local context of healthcare within a given environment.

EMSC AND THE CONTINUUM OF CARE MODEL

EMSC is a U.S. federal initiative designed to reduce child and youth disability and death as a result of severe illness or injury. The EMSC program has developed an operational framework for conceptualizing a systems approach to emergency care for children, known as the *continuum of care model*. The model specifically refers to the seamless care of ill and injured children from the community and medical home through to definitive care and return to the community. It has the following 5 principal components:

1. Prevention
2. Out-of-hospital care, both emergency response and prehospital transport
3. Hospital-based care: emergency center and inpatient unit
4. Interfacility transport, as necessary, for definitive or subspecialty care (see Chapter 66.1)
5. Rehabilitation

This framework can also be applied to discussion of emergency care for children on an global level. With medical infrastructures that may not be consistent or well-organized, or that have been weakened by civil strife, natural disasters, and economic loss, the focus of child health in the developing world has been on prevention and acute care.

APPLYING THE CONTINUUM OF CARE MODEL TO THE DEVELOPING WORLD

Prevention

Infectious Diseases

International child health has focused mainly on reducing preventable childhood illnesses, primarily through immunizations. Enormous advances have been realized in measles, neonatal tetanus, and polio reduction; wild-type smallpox was eradicated in 1978. Although there are advocates for providing primary care interventions (e.g., vaccinations) in the ED, the role of the PEM practitioner in this area of prevention has been limited.

Injuries

Injuries are a leading cause of childhood morbidity and mortality. Unintentional injuries constitute 90% of injury mortality to children ages 5-19 yr and are the cause of 9% of the world's mortality. Intentional injuries, an underrecognized and underreported phenomenon primarily for cultural reasons, make a smaller but significant contribution. Unintentional injuries cause more than 2,000 childhood deaths daily or 950,000 annually worldwide. The burden of these deaths is borne disproportionately by children in middle- and lower-income

countries, where more than 95% of all injury deaths occur. For each of these deaths, many more children are permanently disabled and an even larger number are treated and released without permanent sequelae.

The World Health Organization (WHO) and United Nations Children's Fund (UNICEF) have outlined several proven injury prevention strategies of which child health practitioners in the global community must be aware. The top 3 causes of injury mortality are traffic-related injuries, burns, and drowning. There are 7 specific effective strategies for reducing **road traffic injuries:** a minimum drinking age, appropriate child restraints and seatbelts, helmets for motorcycle and bicycle riders, reduced vehicle speeds around schools and residential areas, running lights on motorcycles, graduated licensing for drivers, and separation of different types of road users. There is insufficient evidence to demonstrate that school-based programs on drunk driving, increased pedestrian visibility, or designated driver programs are effective. Although these strategies have been proven effective, the data are based on research from the United States and may not be generalizable to other countries. It may be difficult to reduce vehicle speeds around schools when there is insufficient infrastructure for street signs. Alternatively, lack of separation of car and bus traffic from bicyclists and pedestrians contributes to unsafe and dangerous road conditions. This is more of a problem in lower- and middle-income countries, where bicycles and motorized 2-wheel vehicles are used to carry children as well as goods, while the drivers negotiate among rapidly moving vehicles. With rising income, these countries have seen increases in both the number of cars and the number of 2-wheeled vehicles, with a corresponding increase in the number of related injuries.

For reducing **drowning deaths**, strategies that have proven effective focus on creating barriers between children and water hazards, such as covering wells, buckets, and other standing sources of water, and placing high fences around pools (see Chapter 74). **Burns** have been addressed by advocating for installation of smoke detectors and lowering the temperature of water from water heaters (see Chapter 75).

For the PEM practitioner, involvement in prevention depends largely on the local epidemiology of injuries and the factors contributing to those injuries. Involvement can include parental and patient education or activism to change local practices through laws and new community standards. Additionally, work can be done with groups of practitioners or healthcare centers to increase capacity to care for injured children. One can also work on a larger scale on projects initiated by a group such as the WHO, UNICEF, or Safe Kids Worldwide, to develop and evaluate intervention strategies that target specific preventable injuries.

Out-of-Hospital Care

Out-of-hospital care comprises access to emergency services, prehospital care, and interfacility transport of patients. Morbidity and mortality arise from delayed or limited access to emergency care, lack of prehospital care, transport without proper monitoring or trained personnel, or delayed transport to a higher level of care. Safe transport of seriously ill children is a neglected global health issue. An emergency response system must address the following links in the patient's care: a communication system with prompt activation of EMS, the correct assessment and initial treatment of the patient, and the rapid transport to definitive care.

Access to Care

When a child is injured or ill, a parent or caretaker must be able to access help and activate EMS. Many countries around the world have dedicated emergency numbers to rapidly dispatch medical, police, or fire services. The simple "112" emergency number has been adopted and is being phased in throughout the European Union member states, to be used to access medical, fire and police services in addition to secondary regional emergency access numbers. The universal U.S. emergency number system 911 today covers the large majority of the country (98%) and has enhanced features of automatically linking the phone number to an address. However, there remain limitations to universal access resulting from absence of phones in some households, unclear addresses in rural areas, and insufficient reach of the emergency system. In low- and middle-income countries, no such universal emergency numbers have been established, requiring access by direct dialing to an ambulance, if such private services exist. In most low- and middle-income countries, the family must bring the ill or injured child to the health facility for stabilization and treatment. For this to occur, families must overcome financial and geographic barriers, which can result in delayed presentation for care. This delay predictably increases the acuity of the illness or injury and associated complications, and decreases the likelihood of full recovery and survival.

Prehospital Care

In regions with maturing EMS systems, there must be adequately trained personnel to stabilize and transport the child to a medical facility. The quality and level of training of such prehospital personnel vary tremendously among countries and within regions of the same country. In urban areas, there is a greater concentration of medical care and therefore a greater opportunity to have strong prehospital training. In most of Asia and sub-Saharan Africa, trained personnel are used primarily to transfer patients between health facilities, and not from the initial site of illness or injury. In most high-income countries, EMS are dispatched to the patient.

A different approach to prehospital work is exemplified by the French EMS, called Service d'Aide Médicale Urgente (SAMU). In this system, a physician is integral to the prehospital team. A physician, typically an emergency medicine specialist in larger areas, will review every call for acuity and can dispatch a physician-led team by ambulance to go to the patient's home to assess, stabilize, and initiate treatment. This Franco-German system is used in other countries, including many in Latin America and Europe. There are no clear data on the cost-effectiveness and patient outcomes associated with delivery of patients to the nearest facility versus bringing hospital resources to the patient. Some research suggests, however, that it is difficult for ambulance-based physicians to maintain their field skills given the relatively low frequency of high-acuity or high-complexity cases.

Around the world, the effort to establish standardized approaches to prehospital care exists primarily in the form of courses to educate EMS and hospital personnel in the emergency management of patients. For trauma care, the WHO manuals *Prehospital Trauma Care Systems* and *Guidelines for Essential Trauma Care* both focus on guidelines for prehospital and trauma care systems that are affordable and sustainable. The AAP course Pediatric Education for Prehospital Professionals is a dynamic, modularized teaching tool designed to provide specific pediatric prehospital education that can be adapted to any EMS system. Table 66-7 lists additional prehospital resources.

Although most middle- and high-income countries have a system of trained EMS workers, low-income countries lack this advanced tier of emergency care. In these countries, commercial drivers, volunteers, and willing bystanders provide the first line of care. Training a cadre of first responders can rely on existing networks of aid or can be drawn from specific populations, such as students, soldiers, or public servants. Training needs to emphasize basic lifesaving and limb-saving interventions, including how to stop bleeding and support breathing, access advanced care, and splint broken limbs. In Ghana, for example, 335 taxi drivers participated in a first-aid course that relied heavily on demonstration and practice rather than knowledge transfer through didactic sessions. Taxi drivers were selected because they already provided much of the transport for injured patients, either voluntarily or for pay by the family. Two years after the course, external evaluators favorably rated the quality of their care in comparison with that of a group of untrained drivers. In rural areas, such first responders become vital in providing emergency interventions when more definitive care is distant. Thus, a system of trained first responders forms the foundation of an effective prehospital system.

Methods of Transport

In many low-income countries, there is no means of transport other than the family's motorized or other type of transport. Health centers may only have 1 vehicle for transport to a higher-level facility. This

vehicle may also be used for outreach primary care services, such as offering immunizations and collecting drugs and equipment from a central supply location, and, sometimes, improperly for personal reasons by local officials or politicians. In large cities, taxis and auto rickshaws are frequently used because they are rapidly available and well disseminated within cities. Where there are organized prehospital systems, different types of vehicles are adapted for emergency transportation, from fully equipped ambulances to basic transport with trained personnel. The WHO recommends identifying transport vehicles in advance, choosing vehicles that can be repaired and maintained locally, and equipping the vehicles according to recognized standards. Therefore the provision of available and appropriately staffed and equipped transport vehicles is crucial to the realization of recommended emergency care plans.

Hospital-Based Care

Once a child has reached a medical facility for the care of an injury or illness, adequate emergency services must be available. In many countries, the ED serves only as a triage area where patients are distinguished by their likely disease process and directed for admission to the corresponding unit within the hospital. Strengthening emergency services includes seeing the ED as a unit where definitive treatment can be provided to the ill and injured child. Critically ill children must receive not only prompt care but also correct care. Such expedience and accuracy are ensured by implementation of an effective triage system, moving the sickest patients to immediate care and standardizing the initial care of emergency conditions.

Triage

Children requiring emergency care frequently are not promptly recognized. Too often, children presenting to EDs are treated on a first-come first-served basis, in an approach that creates long waiting times for critically ill children, a contributor to unnecessary mortality. Medical facilities need to adopt an efficient and effective triage system in order to rapidly respond to the needs of patients and to assign the appropriate amount of resources. To this end, WHO has developed a course entitled Emergency Triage Assessment and Treatment (ETAT). This course teaches health practitioners to triage patients on arrival as having emergency, priority, or nonurgent signs and to provide emergency treatment for life-threatening conditions. ETAT emphasizes the evaluation of a patient's ABCD status to identify emergency situations—the patency of the airway (A), the quality of breathing (B), the quality of circulation and presence of coma or convulsions (C), and the presence of severe dehydration (D).

One of the benefits of the ETAT guidelines is that they can be adapted to centers with limited resources and are applicable to areas with high morbidity and mortality from meningitis, dehydration, malaria, respiratory illness, and malnutrition. Another benefit is that the care algorithms are based on limited diagnostic studies, that is, hemoglobin measurement, blood smear for malaria, and bedside blood glucose testing. Widely accepted triage assessment guidelines are teachable to emergency care staff, and their adoption can provide better organization within a healthcare center. At the Queen Elizabeth Central Hospital in Blantyre, Malawi, for example, the institution of triage and rapid treatment in its emergency care center led to a 50% decrease in the mortality of children within 24 hr of presentation to the hospital, with a further 50% decrease as implementation and practice of triaging patients have continued.

Beyond triage, education on overall emergency center organization is a low-resource intervention that can obviate some of the obstacles to quality care delivery. Additionally, the arrangement of short-stay areas (hydration and infusion rooms) can lessen the burden on inpatient units.

Pediatric-Specific Emergency Centers

Descriptions on the development of pediatric-specific emergency centers are insufficient. Anecdotally, most countries have developed at least 1 pediatric-capable center, usually as part of an academic medical center. The emergency services in these centers are variable, but certainly can be a starting point from which to build overall improvement in pediatric emergency care.

Practitioners

Throughout the world, nurses, paramedics, and nonspecialist physicians provide most of the care to acutely ill or injured children. The majority of sick children attend local clinics or district or central hospitals, where financial and human resources are not always matched to the potential acuity of presenting patient complaints. Nominal supervision is provided to staff attending these patients. Pediatric EDs located in tertiary hospitals are often staffed by training physicians with little or no supervision from faculty, who themselves may have limited exposure to or training in PEM. General hospitals lack dedicated pediatric staff; guidelines as to which patients should be moved to a higher level of care are often not standardized and depend on local influences and/or cultural beliefs about health and illness.

Clinical Guidelines

The Integrated Management of Childhood Illnesses (IMCI) guidelines were developed by the WHO and UNICEF to provide assistance in the initial triage and management of the presenting signs and symptoms of the major killers of the under–5 yr population in first-level health facilities (e.g., clinics, health centers, and outpatient departments of hospitals). The flow charts within each chapter of the IMCI manuals allow easy accessibility to materials that can enhance education and outreach to less experienced health workers.

Evaluations in various countries of the implementation of IMCI guidelines have shown improvements in health worker performance and quality of care as well as decreases in delay in treatment and mortality of under–5 yr children. These guidelines also dramatically reduce the cost of healthcare. The WHO website provides all the necessary implementation tools, including course manuals and evaluation tools.

Trauma

Morbidity and mortality from trauma is one of the most prevalent problems for children worldwide. Trauma care presents the challenge of sequential, often simple, interventions that must be performed in a timely manner to limit the severity of the outcome. However, with lack of specific training, signs and symptoms of pediatric trauma may go unrecognized or may be underappreciated. Trauma courses such as Advanced Trauma Life Support are educational tools that can be disseminated to improve the quality of care at emergency centers worldwide. For low-resource settings, the WHO has developed the Integrated Management for Emergency and Essential Surgical Care toolkit, which provides clear directions and reasoning for the initial care of injured patients. Not expressly addressed in the Advanced Trauma Life Support course is specific concern about child abuse as the cause of trauma. This is an area of pediatric care that many countries do not yet address in their medical training, their law enforcement, or their judicial systems. The epidemiologic need for reliable trauma registries is great, as is the need to identify personnel with trauma management skill sets and dedicated trauma centers to serve as higher-level referral sites.

Equipment

Pediatric emergency textbooks, pediatric and emergency medicine professional organizations, WHO, and nongovernmental and governmental health organizations have all published pediatric emergency equipment guidelines, for a variety of settings in which acutely ill and injured children would present. Although these equipment guidelines may represent minimum supplies to treat the widest variety of pediatric emergencies, the roles of substitution and improvisation often provide for equivalent function of recommended supplies.

Inpatient Services

After the initial stabilization, children requiring ongoing care are admitted to the hospital. The quality of inpatient services varies greatly depending on institutional and provider experience, comfort with pediatric conditions, and the resources available to treat them. The WHO has produced the *Pocket Book of Hospital Care for Children,*

which is based on IMCI guidelines and focuses on inpatient management of high-morbidity/high-mortality illnesses common in developing countries.

HUMANITARIAN DISASTERS

Children are a vulnerable population who experience disproportionate suffering during humanitarian emergencies, either natural (earthquakes, tsunamis, hurricanes, floods, and droughts) or manmade (armed conflicts, terrorist attacks). The under–5 yr population is especially susceptible to infectious diseases, malnutrition, and trauma following disasters. The Rainbow Center for Global Child Health at the Case Western Reserve University School of Medicine offers a training course, Management of Humanitarian Emergencies: Focus on Children and Families, that concentrates on the needs of children in disasters. The intent of the Center is to educate and train health professionals, relief workers, and policymakers to recognize and address the unique needs of children affected by manmade and natural disasters worldwide. The AAP also maintains a CHILDisaster Network, which acts as an electronic database of child health professionals with education and experience in humanitarian emergencies. Nongovernmental organizations can access the database to solicit practitioners to aid in disaster response.

The WHO's *Manual for the Health Care of Children in Humanitarian Emergencies* is based on IMCI guidelines and addresses the emergency care of children in disaster situations in which hospital facilities and resources are not immediately available. It goes beyond the IMCI guidelines by discussing initial assessment and management of trauma, burns, and poisonings. Preexisting IMCI guidelines assumed a functioning health system that facilitated the referral of children, which may not be available in all emergency situations. This manual also includes the initial management of severe conditions, such as injuries, burns, neonatal illness, and psychosocial problems, which are considered high priority in acute care settings.

Exchange and Dissemination of Information

The WHO established the HINARI (Health InterNetwork Access to Research Initiative) program to allow free or reduced-cost access to more than 6,200 journal publications. This Internet access is made available to the 108 countries with gross national income per capita less than $3,500. For middle-income countries not meeting the financial eligibility, Internet access continues to be a barrier, and resources may be limited to out-of-date textbooks and journals.

Another valuable tool is the website Pemdatabase.org. This nonproprietary site was started as an online resource for PEM practitioners. It contains links to PEM abstracts and articles, evidence-based reviews, pediatric resuscitation websites, relevant journals, as well as PEM conferences and professional organizations.

Chapter 67

Pediatric Emergencies and Resuscitation

Mary E. Hartman and Ira M. Cheifetz

Injuries are the leading cause of death in American children and young adults and are responsible for more childhood deaths than all other causes combined (see Chapter 5.1). Children are particularly vulnerable to injury for a number of reasons, including their small size, relative physical uncoordination, and limited ability to predict or understand danger. In addition, the immaturity of their developing bones, ligaments, and muscles; their thin body walls; and their relatively large heads, compared with total body surface area, make young children susceptible to serious or fatal injury from falls and collisions.

Most injuries in childhood are unintentional, and many are preventable. Motor vehicle–related injuries are the most common cause of unintentional injury and death for U.S. children, many of which are related to speeding, aggressive driving, failure to use proper passenger restraints, and/or alcohol. Consistent use of bicycle helmets could reduce the severity of head injuries, the leading cause of death when a bicyclist is struck by a car, by more than 80%. Four-sided fencing around swimming pools and use of flotation devices for every passenger in a boat could greatly reduce the risk of drowning, the second leading cause of accidental death in children younger than 5 yr and the third major cause of death in adolescents. Serious injuries can become fatal when appropriate medical care is delayed.

Rapid, effective bystander cardiopulmonary resuscitation (CPR) for children is associated with survival rates as high as 70%, with good neurologic outcome. However, bystander CPR is still provided for less than 50% of children who experience cardiac arrest outside medical settings. This has led to long-term survival rates of <40%, with many survivors suffering a poor neurologic outcome.

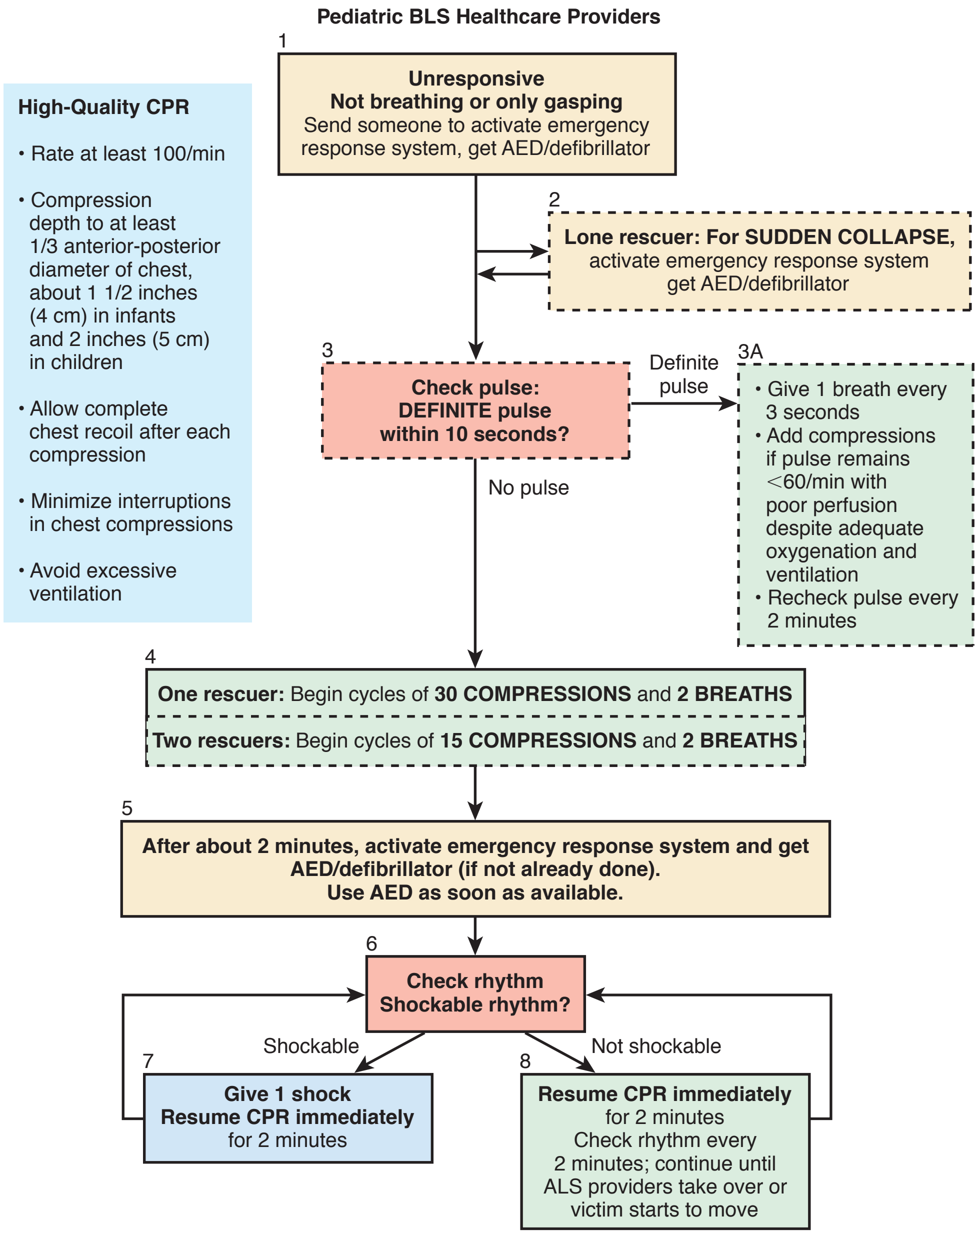
APPROACH TO THE EMERGENCY EVALUATION OF A CHILD

The first response to a pediatric emergency of any cause is a systematic, rapid **general assessment** of the scene and the child to identify immediate threats to the child, care providers, or others. If an emergency is identified, the emergency response system (emergency medical services [EMS]) should be activated immediately. Care providers should then proceed through **primary**, **secondary**, and **tertiary assessments** as allowed by the child's condition, safety of the scene, and resources available. This standardized approach provides organization to what might otherwise be a confusing or chaotic situation and reinforces an organized thought process for care providers. If, at any point in these assessments, the caregiver identifies a life-threatening problem, the assessment is halted and lifesaving interventions are begun. Further assessment and intervention should be delayed until other caregivers arrive or the condition is successfully treated.

General Assessment

Upon arrival at the scene of a compromised child, a caregiver's first task is a quick survey of the scene itself. Is the rescuer or child in imminent danger because of circumstances at the scene (fire, high-voltage electricity)? If so, can the child be safely extricated to a safe location for assessment and treatment? Can the child be safely moved with the appropriate precautions (i.e., cervical spine protection), if indicated? A rescuer is expected to proceed only if these safety conditions have been met.

Once the caregiver and patient's safety has been ensured, the caregiver performs **a rapid visual survey** of the child, assessing the child's **general appearance and cardiopulmonary function**. This action should be very quick (only a few seconds) and should include assessment of (1) general appearance (determining color, tone, alertness, and responsiveness); (2) adequacy of breathing (distinguishing between normal, comfortable respirations and respiratory distress or apnea); and (3) adequacy of circulation (identifying cyanosis, pallor, or mottling). A child found unresponsive from an *unwitnessed* collapse should be approached with a gentle touch and the verbal question, "Are you OK?" If there is no response, the caregiver should immediately shout for help and send someone to both activate the emergency response system (EMS) and locate an automated external defibrillator (AED) (Fig. 67-1). The provider should then determine whether the child is breathing and, if not, provide 2 rescue breaths as described later under "Recognition and Treatment of Respiratory Distress and Failure." If the child is adequately breathing, then the circulation is quickly assessed. Any child with a heart rate below 60 beats/min or without a pulse requires immediate CPR, as described under



Note: The boxes bordered with dashed lines are performed by healthcare providers and not by rescuers

Figure 67-1 **Pediatric basic life support algorithm.** AED, automated external defibrillator; ALS, advanced life support; CPR, cardiopulmonary resuscitation. *(From Berg MD, Schexnayder SM, Chameides L, et al: 2010 American Heart Association guidelines for cardiopulmonary resuscitation and emergency cardiovascular care, part 13,* Circulation *122[Suppl 3]:S862–S875, 2010, Fig. 3, p. S866.)*

"Recognition and Management of Cardiac Arrest." If the caregiver *witnesses* the sudden collapse of a child, the caregiver should have a higher suspicion for a sudden cardiac event. In this case, rapid deployment of an AED is of paramount importance. The provider should very briefly delay care of the child to activate EMS and locate the nearest AED.

Primary Assessment

Once the emergency response system has been activated and the child is determined not to need CPR, the caregiver should proceed with a primary assessment that includes a **brief, hands-on assessment of cardiopulmonary and neurologic function and stability**. This assessment includes a limited physical exam, evaluation of vital signs, and measurement of pulse oximetry if possible. Again, a standardized approach is best. The American Heart Association, in its Pediatric Advanced Life Support (PALS) curriculum, supports the structured format of **Airway, Breathing, Circulation, Disability, Exposure (ABCDE)**. The goal of the primary assessment is to obtain a focused, systems-based assessment of the child's injuries or abnormalities, so that resuscitative efforts can be directed to these areas; if the caregiver identifies a life-threatening abnormality, further evaluation is postponed until appropriate corrective action has been taken.

The exam and vital sign data can be interpreted only if the caregiver has a thorough understanding of normal values. In pediatrics, normal respiratory rate, heart rate, and blood pressure have age-specific norms (Table 67-1). These ranges can be difficult to remember, especially if used infrequently. However, several standard principals apply: (1) no child's respiratory rate should be >60 breaths/min for a sustained period; (2) normal heart rate is roughly 2-3 times normal respiratory rate for age; and (3) a simple guide for pediatric blood pressure is that

Table 67-1 Normal Vital Signs According to Age

AGE	HEART RATE (beats/min)	BLOOD PRESSURE (mm Hg)	RESPIRATORY RATE (breaths/min)
Premature	120-170*	55-75/35-45†	40-70‡
0-3 mo	100-150*	65-85/45-55	35-55
3-6 mo	90-120	70-90/50-65	30-45
6-12 mo	80-120	80-100/55-65	25-40
1-3 yr	70-110	90-105/55-70	20-30
3-6 yr	65-110	95-110/60-75	20-25
6-12 yr	60-95	100-120/60-75	14-22
12+ yr	55-85	110-135/65-85	12-18

*In sleep, infant heart rates may drop significantly lower, but if perfusion is maintained, no intervention is required.
†A blood pressure cuff should cover approximately two-thirds of the arm; too small a cuff yields spuriously high pressure readings, and too large a cuff yields spuriously low pressure readings.
‡Many premature infants require mechanical ventilatory support, making their spontaneous respiratory rate less relevant.

the lower limit of systolic blood pressure should be ≥60 mm Hg for neonates; ≥70 mm Hg for 1 mo-1 yr olds; ≥70 mm Hg + (2 × age) for 1-10 yr olds; and ≥90 mm Hg for any child older than 10 yr.

Airway and Breathing

The most common precipitating event for cardiac instability in infants and children is respiratory insufficiency. Therefore, rapid assessment of respiratory failure and immediate restoration of adequate ventilation and oxygenation remain the first priority in the resuscitation of a child. Using a systematic approach, the caregiver should first assess whether the child's airway is patent and maintainable. A healthy, patent airway is open and unobstructed, allowing normal respiration without noise or effort. A maintainable airway is one that is either already patent or can be made patent with a simple maneuver. To assess airway patency, the provider should look for breathing movements in the child's chest and abdomen, listen for breath sounds, and feel the movement of air at the child's mouth and nose. Abnormal breathing sounds (i.e., snoring or stridor), increased work of breathing, and apnea are all findings potentially consistent with airway obstruction. If there is evidence of airway obstruction, then maneuvers to relieve the obstruction should be instituted before the caregiver proceeds to evaluate the child's breathing (see under "Recognition and Treatment of Respiratory Distress and Failure").

Assessment of breathing includes evaluation of the child's respiratory rate, respiratory effort, abnormal sounds, and pulse oximetry. Normal breathing appears comfortable, is quiet, and occurs at an age-appropriate rate. Abnormal respiratory rates include apnea and rates that are either too slow (bradypnea) or too fast (tachypnea). **Bradypnea and irregular respiratory patterns require urgent attention, as they are often signs of impending respiratory failure and apnea.** Signs of increased respiratory effort include nasal flaring, grunting, chest or neck muscle retractions, head bobbing, and "seesaw" respirations. Hemoglobin oxygen desaturation, as measured by pulse oximetry, often accompanies parenchymal lung disease apnea or airway obstruction. However, providers should keep in mind that adequate perfusion is required to produce a reliable oxygen saturation measurement. A child with low oxygen saturation is a child in distress. Central cyanosis is a sign of severe hypoxia and indicates an emergent need for oxygen supplementation and respiratory support.

Circulation

Cardiovascular function is assessed by evaluation of skin color and temperature, heart rate, heart rhythm, pulses, capillary refill time, and blood pressure. In nonhospital settings, much of the important information can be obtained without measuring the blood pressure; lack of blood pressure data should not prevent the provider for determining adequacy of circulation or implementing a lifesaving response. Mottling, pallor, delayed capillary refill, cyanosis, poor pulses, and cool extremities are all signs of diminished perfusion and compromised cardiac output. Tachycardia is the earliest and most reliable sign of shock, but is itself fairly nonspecific and should be correlated with other components of the exam, such as weakness, threadiness, and absence of pulses. An age-specific approach to pulse assessment will yield best results.

Table 67-2 AVPU Neurologic Assessment

A	The child is awake, alert, and interactive with parents and care providers
V	The child responds only if the care provider or parents call the child's name or speak loudly
P	The child responds only to painful stimuli, such as pinching the nail bed of a toe or finger
U	The child is unresponsive to all stimuli

Adapted and modified from Teasdale G, Jennett B: Assessment of coma and impaired consciousness: a practical scale, Lancet *2:81–84, 1974.*

Disability

In the setting of a pediatric emergency, *disability* refers to a child's neurologic function in terms of the level of consciousness and cortical function. Standard evaluation of a child's neurologic condition can be done quickly with an assessment of pupillary response to light (if one is available) and use of either of the standard scores used in pediatrics: the Alert, Verbal, Pain, Unresponsive (AVPU) Pediatric Response Scale and the Glasgow Coma Scale (GCS) (Tables 67-2, 67-3, and 68-1). The causes of decreased level of consciousness in children are numerous and include conditions as diverse as respiratory failure with hypoxia or hypercarbia, hypoglycemia, poisonings or drug overdose, trauma, seizures, infection, and shock. **Most commonly, an ill or injured child has an altered level of consciousness because of respiratory compromise, circulatory compromise, or both**. Any child with a depressed

level of consciousness should be immediately assessed for abnormalities in cardiorespiratory status.

The Alert, Verbal, Pain, Unresponsive Pediatric Response Scale. The AVPU scoring system is used to determine both a child's level of consciousness and cerebral cortex function. Unlike the GCS (see later), the AVPU scale is not developmentally dependent—a child does not have to understand spoken language or follow commands, merely respond to a stimulus. The child is scored according to the amount of stimulus required to get a response, from alert (no stimulus, the child is already awake and interactive) to unresponsive (child does not respond to any stimulus) (see Table 67-2).

The Glasgow Coma Scale. Although the GCS has not been validated as a prognostic scoring system for infants and young children as it has been in adults, it is commonly used in the assessment of pediatric patients with an altered level of consciousness. The GCS is the most widely used method of evaluating a child's neurologic function and has 3 components. Individual scores for eye opening, verbal response, and motor response are added together, with a maximum of 15 points (see Table 67-3). Patients with a GCS score ≤8 require aggressive management, including stabilization of the airway and breathing with endotracheal intubation and mechanical ventilation, respectively, and, if indicated, placement of an intracranial pressure monitoring device. The Full Outline of Unresponsiveness (FOUR) score is another useful assessment and monitoring tool (see Table 68-1).

Exposure

Exposure is the final component of the pediatric primary assessment. This component of the exam is reached only after the child's airway, breathing, and circulation have been assessed and determined to be stable or have been stabilized through simple interventions. In this setting, *exposure* stands for the dual responsibility of the provider to both expose the child to assess for previously unidentified injures and consider prolonged exposure in a cold environment as a possible cause of hypothermia and cardiopulmonary instability. The provider should undress the child (as is feasible and reasonable) to perform a focused physical exam, assessing for burns, bruising, bleeding, joint laxity, and fractures. If possible, the provider should assess the child's temperature. All maneuvers should be performed with careful maintenance of cervical spine precautions.

Secondary Assessment

For care providers in community or outpatient settings, transfer of care of a child to emergency or hospital personnel may occur before a full secondary assessment is possible. However, before the child is removed from the scene and separated from witnesses or family, a brief history should be obtained for medical providers at the accepting facility. **The components of a secondary assessment include a focused history and focused physical exam.**

The history should be targeted to information that could explain cardiorespiratory or neurologic dysfunction and should take the form of a **SAMPLE history (Signs/symptoms, Allergies, Medications, Past medical history, timing of Last meal, and Events leading to this situation)**. Medical personnel not engaged in resuscitative efforts can be dispatched to elicit history from witnesses or relatives. The physical exam during the secondary assessment is a thorough head-to-toe exam, although the severity of the child's illness or injury could necessitate curtailing portions of the exam or postponing nonessential elements until a later time.

Tertiary Assessment

The tertiary assessment occurs in a hospital setting, where ancillary laboratory and radiographic assessments contribute to a thorough understanding of the child's condition. A basic blood chemistry profile, complete blood count, liver function tests, coagulation studies, and arterial blood gas analyses give fairly broad (but somewhat nonspecific) estimates of renal function, acid–base balance, cardiorespiratory function, and presence or absence of shock. Chest radiographs can be useful to evaluate both the heart and lungs, although more detailed estimates of heart function and cardiac output can be made with echocardiography. Arterial and central venous catheters can be placed to monitor arterial and central venous pressure (see under "Vascular Access").

RECOGNITION AND TREATMENT OF RESPIRATORY DISTRESS AND FAILURE

The goals of initial management of respiratory distress or failure are to rapidly stabilize the child's airway and breathing and to identify the cause of the problem so that further therapeutic efforts can be appropriately directed.

Airway Obstruction

Children <5 yr old are particularly susceptible to foreign-body aspiration and choking. Liquids are the most common cause of choking in infants, whereas small objects and food (e.g., grapes, nuts, hot dogs, candies) are the most common source of foreign bodies in the airways of toddlers and older children. A history consistent with foreign-body aspiration is considered diagnostic. Any child in the proper setting with the sudden onset of choking, stridor, or wheezing has foreign-body aspiration until proven otherwise.

Airway obstruction is treated with a sequential approach, starting with the head-tilt/chin-lift maneuver to open and support the airway, followed by inspection for a foreign body, and finger-sweep clearance or suctioning if one is visualized (Fig. 67-2). Blind suctioning or finger sweeps of the mouth **are not recommended**. A nasopharyngeal airway or oropharyngeal airway can be inserted for airway support, if indicated. A conscious child suspected of having a partial foreign-body obstruction should be permitted to cough spontaneously until coughing is no longer effective, respiratory distress and stridor increase, or the child becomes unconscious.

If the child becomes unconscious, the child should be gently placed on the ground, supine. The provider should then open the airway with the head-tilt/chin-lift maneuver and attempt mouth-to-mouth ventilation (Figs. 67-3 and 67-4). If ventilation is unsuccessful, the airway is repositioned, and ventilation attempted again. If there is still no chest rise, attempts to remove a foreign body are indicated. In an infant <1 yr old, a combination of 5 back blows and 5 chest thrusts is administered

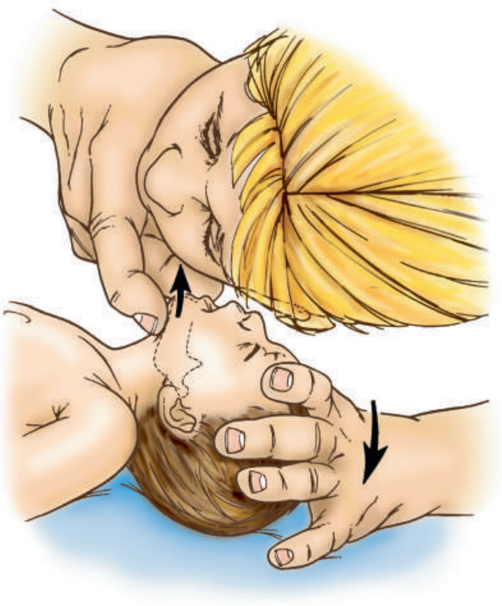

Figure 67-2 Opening the airway with the head-tilt/chin-lift maneuver. One hand is used to tilt the head, extending the neck. The index finger of the rescuer's other hand lifts the mandible outward by lifting the chin. Head-tilt should not be performed if a cervical spine injury is suspected. *(From Guidelines for cardiopulmonary resuscitation and emergency cardiac care. Emergency Cardiac Care Committee and Subcommittees, American Heart Association. Part V. Pediatric basic life support,* JAMA *268:2251–2261, 1992.)*

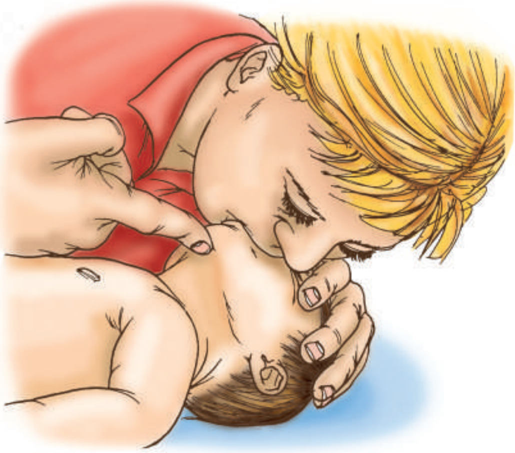

Figure 67-3 Rescue breathing in an infant. The rescuer's mouth covers the infant's nose and mouth, creating a seal. One hand performs the head-tilt while the other hand lifts the infant's jaw. Avoid head-tilt if the infant has sustained head or neck trauma. *(From Guidelines for cardiopulmonary resuscitation and emergency cardiac care. Emergency Cardiac Care Committee and Subcommittees, American Heart Association. Part V. Pediatric basic life support,* JAMA *268:2251–2261, 1992.)*

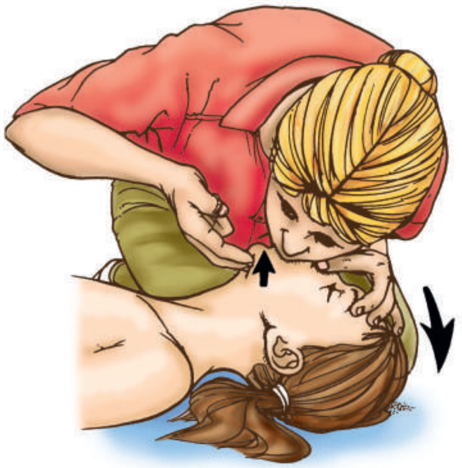

Figure 67-4 Rescue breathing in a child. The rescuer's mouth covers the child's mouth, creating a mouth-to-mouth seal. One hand maintains the head-tilt; the thumb and forefinger of the same hand are used to pinch the child's nose. *(From Guidelines for cardiopulmonary resuscitation and emergency cardiac care. Emergency Cardiac Care Committee and Subcommittees, American Heart Association. Part V. Pediatric basic life support,* JAMA *268:2251–2261, 1992.)*

(Fig. 67-5). After each cycle of back blows and chest thrusts, the child's mouth should be visually inspected for the presence of the foreign body. If identified within finger's reach, it should be removed with a gentle finger sweep. If no foreign body is visual, ventilation is again attempted. If this is unsuccessful, the head is repositioned, and ventilation attempted again. If there is no chest rise, the series of back blows and chest thrusts is repeated.

For a conscious child >1 yr old, providers should give a series of 5 abdominal thrusts (Heimlich maneuver) with the child standing or sitting (Fig. 67-6); this should occur with the child lying down if unconscious (Fig. 67-7). After the abdominal thrusts, the airway is examined for a foreign body, which should be removed if visualized. If no foreign body is seen, the head is repositioned, and ventilation attempted. If it is unsuccessful, the head is repositioned and ventilation is attempted again. If these efforts are unsuccessful, the Heimlich sequence is repeated.

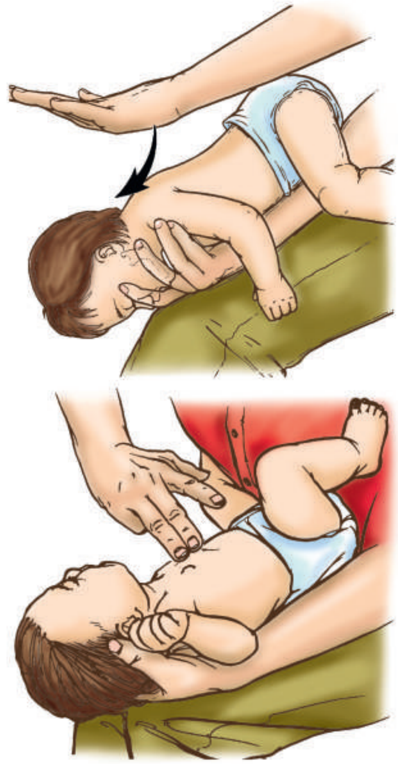

Figure 67-5 Back blows *(top)* and chest thrusts *(bottom)* to relieve foreign-body airway obstruction in the infant. *(From Guidelines for cardiopulmonary resuscitation and emergency cardiac care. Emergency Cardiac Care Committee and Subcommittees, American Heart Association. Part V. Pediatric basic life support,* JAMA *268:2251–2261, 1992.)*

Emergency Cardiac Care Committee and Subcommittees, American Heart Association. Part V. Pediatric basic life support,* JAMA *268:2251–2261, 1992.)*

Airway Narrowing

Airway obstruction can also be caused by airway narrowing, in both the upper and lower airways. *Upper airway obstruction* refers to narrowing of the extrathoracic portion of the airway, including the oropharynx, larynx, and trachea. In the upper airways, narrowing is most often caused by airway edema (croup or anaphylaxis). Lower airway disease affects all intrathoracic airways, notably the bronchi and bronchioles. In the lower airways, bronchiolitis and acute asthma exacerbations are the major contributors to intrathoracic airway obstruction in children, causing airway narrowing through a combination of airway swelling, mucus production, and circumferential smooth muscle constriction of smaller airways.

Airway support for these processes is dictated by both the underlying condition and the clinical severity of the problem. In cases of mild upper airway obstruction, the child has minimally elevated work of breathing (evidenced by tachypnea and few to mild retractions). Stridor, if present at all, should be audible with only coughing or activity. Children with these findings can be supported with nebulized cool mist and supplemental oxygen as needed. In cases with moderate obstruction, in which the child has a higher work of breathing and more pronounced stridor, nebulized racemic epinephrine and oral or intravenous (IV) dexamethasone can be added. Children with severe upper airway obstruction have marked retractions, prominent stridor, and decreased air entry on auscultation of the lung fields. Most children with significant airway obstruction are also hypoxic, and many appear dyspneic and agitated. A child in severe distress needs to be closely observed, as the signs of impending respiratory failure may be initially confused with improvement. Stridor becomes quieter and retractions less prominent when a child's respiratory effort begins to diminish. The child in respiratory failure can be distinguished from one who is improving by evidence of poor air movement on auscultation and lethargy or decreased level of consciousness from hypercarbia, hypoxia, or both. When anaphylaxis is suspected as the cause for upper airway edema, providers should administer an intramuscular or IV dose of epinephrine as needed (see Chapter 149). No matter the cause, any child in impending respiratory failure should be prepared for endotracheal intubation and respiratory support.

In cases of lower airway obstruction, therapies are targeted to both relieving the obstruction and reducing the child's work of breathing. Inhaled bronchodilators, such as albuterol, augmented by oral or IV corticosteroids, remain the mainstay of therapy in settings of mild to moderate acute distress caused by lower airway obstruction. Children with more significant obstruction appear dyspneic, with tachypnea, retractions, and easily audible wheezing. In these cases, the addition of an anticholinergic agent, such as nebulized ipratropium bromide, or a smooth muscle relaxant, such as magnesium sulfate, may provide further relief, although the evidence for these measures remains controversial (see Chapter 144). Supplemental oxygen and IV fluid hydration can also be useful adjuncts. As in cases of upper airway obstruction, impending respiratory failure in children with lower airway obstruction can be insidious. When diagnosed early in a school-age child who is cooperative, respiratory failure can be averted through judicious use of noninvasive support, with continuous positive airway pressure (CPAP), bilevel positive airway pressure (BiPAP), or heliox (combined helium-oxygen therapy). Endotracheal intubation should be performed only by skilled providers, preferably in a hospital setting, because there is a high risk of respiratory and circulatory compromise in patients with lower airway obstruction during the procedure.

Parenchymal Lung Disease

Parenchymal lung disease includes a heterogeneous list of conditions, such as pneumonia, acute respiratory distress syndrome, pneumonitis, bronchiolitis, bronchopulmonary dysplasia, cystic fibrosis, and pulmonary edema. The commonalities of these conditions are their effects on the small airways and alveoli, including inflammation and exudation leading to consolidation of lung tissue, decreased gas exchange, and increased work of breathing. Clinical management of these conditions includes specific treatment as indicated (i.e., antibiotics for bacterial pneumonia) and supportive care in the form of supplemental oxygen, noninvasive respiratory support (with CPAP or BiPAP), or invasive mechanical ventilation.

Advanced Airway Management Techniques

Bag-Valve-Mask Positive Pressure Ventilation

Rescue breathing with a bag-valve-mask apparatus can be as effective as endotracheal intubation and safer when the provider is inexperienced with intubation. Bag-valve-mask ventilation itself requires training to ensure that the provider is competent to select the correct mask size, open the child's airway, form a tight seal between the mask and the child's face, deliver effective ventilation, and assess the effectiveness of the ventilation. An appropriately sized mask is one that fits over the child's mouth and nose but does not extend below the chin or over the eyes (Fig. 67-8). An adequate seal is best achieved via a combination "C–E" grip on the mask, in which the thumb and index finger form the letter "C" on top of the mask, pressing the mask downward onto the child's face, and the remaining 3 fingers form an "E" grip under the child's mandible, holding the jaw forward and extending the head up toward the mask. Using this method, the care provider can secure the mask to the child's face with 1 hand and use the other hand to compress the ventilation bag (Fig. 67-9).

The provider may have to move the head and neck through a range of positions to find the one that best maintains airway patency and allows maximal ventilation. In infants and young children, optimal ventilation is often provided when the child's head is in the neutral "sniffing" position without hyperextension of the head (Fig. 67-10). Poor chest rise and persistently low oxygen saturation values indicate inadequate ventilation. In this setting, the care provider should recheck the mask's seal on the child's face, reposition the child's head, and consider suctioning the airway if indicated. If these maneuvers do not restore ventilation, then the provider should consider endotracheal intubation.

Endotracheal Intubation

A child requires intubation when at least 1 of these conditions exists: (1) the child is unable to maintain airway patency or protect the airway against aspiration (as occurs in settings of neurologic compromise); (2) the child is failing to maintain adequate oxygenation; (3) the child is failing to control blood carbon dioxide levels and maintain safe

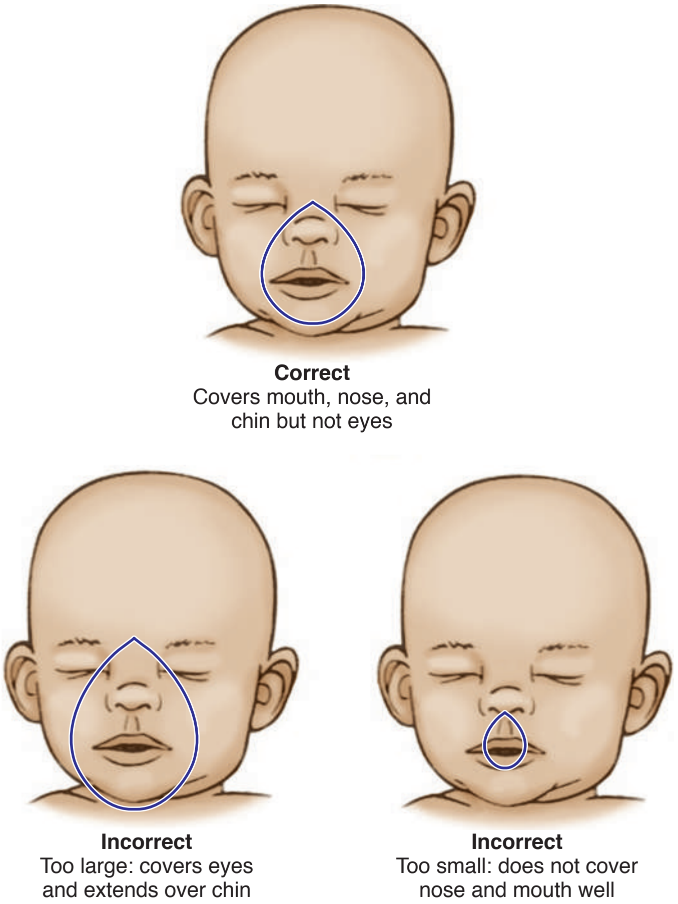

Figure 67-8 **Appropriate sizing technique for pediatric bag-valve-mask apparatus.** *(From American Academy of Pediatrics and the American Heart Association; Kattwinkel J (ed):* Textbook of Neonatal Resuscitation, *ed 6. Elk Grove, IL: American Academy of Pediatrics, 2011. Fig 3-17.)*

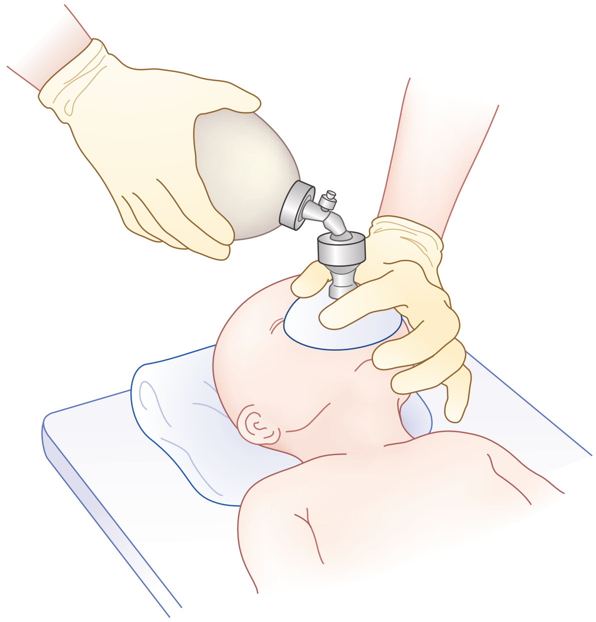

Figure 67-9 "C–E" grip to secure bag-valve-mask to a child's face with appropriate seal.

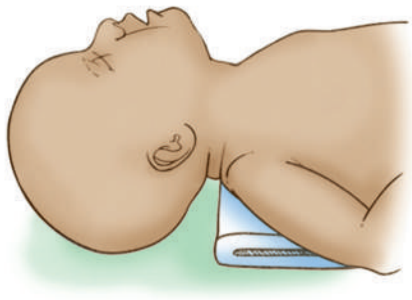

Figure 67-10 **Appropriate head position for bag-valve-mask ventilation.** *(From American Academy of Pediatrics and the American Heart Association; Kattwinkel J (ed):* Textbook of Neonatal Resuscitation, *ed 6. Elk Grove, IL: American Academy of Pediatrics, 2011. Fig 3-19.)*

acid–base balance; (4) sedation and/or paralysis is required for a procedure; and (5) care providers anticipate a deteriorating course that will eventually lead to any of the first 4 conditions. There are few *absolute contraindications* to tracheal intubation, but experts generally agree that in settings of known complete airway obstruction, endotracheal intubation should be avoided, and emergency cricothyroidotomy performed instead. Another important consideration is to ensure that caregivers provide appropriate cervical spine protection during the intubation procedure when neck or spinal cord injury is suspected.

The most important phase of the intubation procedure is the preprocedure preparation, when the provider ensures all the equipment and staff needed for safe intubation are present and functioning. An easy pneumonic for this is **SOAP MM**: suction (Yankauer suction catheter attached to wall suction); oxygen (both preoxygenation of the patient and devices needed to deliver oxygen, such as a bag-valve-mask device); airway (appropriately sized endotracheal tube and laryngoscope); people (all those needed during and immediately after the procedure, such as respiratory therapists and nurses); monitor (to monitor the child's oxygen saturation, heart rate, and blood pressure); and medications (to sedate the child and allow the provider to control the airway). A simple formula for selecting the appropriately sized endotracheal tube (ET) is as follows:

$$\text{Uncuffed ET size (in mm)} = \left(\frac{\text{age in years}}{4}\right) + 4$$

Analgesia is recommended to reduce metabolic stress, discomfort, and anxiety during intubation. Pretreatment with a sedative, an analgesic, and possibly a muscle relaxant is recommended unless the situation is an emergency (i.e., apnea, asystole, unresponsiveness) and the administration of drugs would cause an unacceptable delay.

Because many intubations in critically ill children are emergency procedures, caregivers should be prepared for rapid sequence intubation (RSI) (Fig. 67-11; Table 67-4). The goals of RSI are to induce anesthesia and paralysis and to complete intubation quickly. This approach minimizes elevations of intracranial pressure and blood pressure that may accompany intubation in awake or lightly sedated patients. Because the stomach generally cannot be emptied before RSI, the Sellick maneuver (downward pressure on the cricoid cartilage to compress the esophagus against the vertebral column) should be used to prevent aspiration of gastric contents.

Once the patient is intubated, proper ET placement should be assessed by auscultation of breath sounds, evidence of symmetric chest rise, and analysis of exhaled carbon dioxide (CO_2) by a colorimetric device placed within the respiratory tubing near the ET or a device that directly measures carbon dioxide elimination (i.e., capnogram or capnograph). Chest radiography is necessary to confirm appropriate tube position.

RECOGNITION AND MANAGEMENT OF SHOCK

In simple terms, shock occurs when oxygen and nutrient delivery to the tissues is inadequate to meet metabolic demands (see Chapter 70).

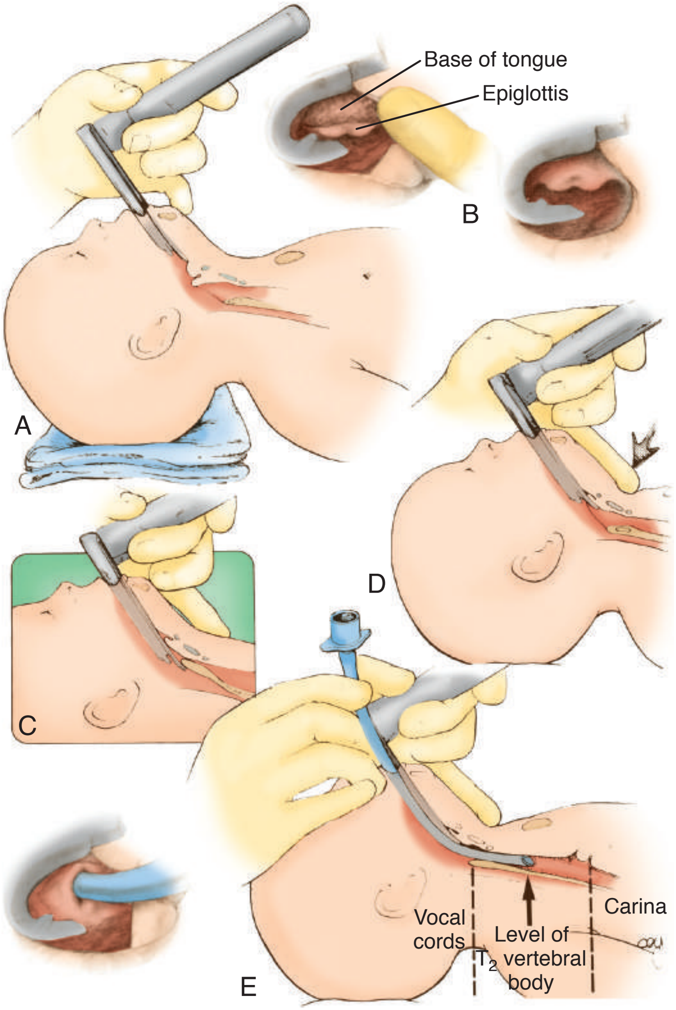

Figure 67-11 *A-E,* Intubation technique. *(From Fleisher G, Ludwig S:* Textbook of pediatric emergency medicine, *Baltimore, 1983, Williams & Wilkins, p. 1250.)*

The definition of shock does not include hypotension, and it is important for care providers to understand that **shock does not begin when blood pressure drops; it merely worsens and becomes more difficult to treat once blood pressure is abnormal.**

Early *compensated* shock, whereby oxygen delivery is mostly preserved through compensatory mechanisms, is defined by the presence of normal blood pressure. When compensatory mechanisms fail, the shock progresses to *decompensated* shock, which is defined by hypotension and organ dysfunction. In *irreversible* shock, organ failure progresses and death ensues.

Shock is also often described according to the underlying pathophysiology, which dictates the appropriate therapeutic response. *Hypovolemic shock* is the most common type of shock in children worldwide, usually related to fluid losses from severe diarrhea. Hemorrhage is a cause of hypovolemic shock after trauma or intestinal hemorrhage. When hypovolemia occurs as a result of third spacing of intravascular fluids into the extravascular compartment, the shock is described as *distributive shock*. The most common causes of distributive shock are sepsis and burn injuries, in which release of inflammatory cytokines causes massive capillary leak of fluid and proteins, leading to low oncotic pressure and intravascular volume. In settings of profound myocardial dysfunction, a child has tissue hypoperfusion from *cardiogenic shock*. The most common causes of cardiogenic shock are congenital heart disease, myocarditis, and cardiomyopathies. *Obstructive shock* occurs when cardiac output is lowered by obstruction of blood flow to the body, as occurs when a ductus arteriosus closes in a child with ductus-dependent systemic blood flow in pericardial tamponade, tension pneumothorax, or massive pulmonary embolism.

The evaluation of a child in shock should proceed as described in the preceding sections on primary, secondary, and tertiary assessments. If the child presents in a hospital setting, providers should obtain central venous and arterial access to permit a more thorough laboratory assessment of all organ systems, including studies of renal and liver function, acid–base balance and presence of lactic acidosis, hypoxemia and/or hypercapnia, and evidence of coagulopathy or disseminated intravascular coagulation. Chest radiography and more sophisticated assessments, such as echocardiography, may also be useful. Respiratory and cardiovascular support should be provided as indicated.

The treatment of shock focuses on the modifiable determinants of oxygen delivery while reducing the imbalance between oxygen demand and supply. A multipronged approach is recommended; it consists of optimizing the oxygen content of the blood, improving the volume and distribution of cardiac output, correcting metabolic derangements, and reducing oxygen demand. Blood oxygen content is maximized when hemoglobin values are normal and 100% of available hemoglobin is saturated with oxygen. Transfusion should be considered in the presence of hemorrhagic or distributive shock, in which crystalloid volume resuscitation has led to hemodilution and anemia. High oxygen saturations may be achieved by simple maneuvers such as oxygen administration via nasal cannula or face mask, but supportive measures that provide positive pressure, such as CPAP, BiPAP, or even mechanical ventilation, may be necessary. Therapies to increase cardiac output should be selected on the basis of underlying pathophysiology. For hypovolemic and distributive shock, aggressive volume resuscitation, guided by arterial and central venous pressures, is the mainstay of therapy. In obstructive shock, relief of the obstruction is critical. The ductus arteriosus can often be reopened with prostaglandin administration, and tamponade physiology can be relieved with appropriate drain placement, as described under "Nonvascular Emergency Procedures."

RECOGNITION OF BRADYARRHYTHMIAS AND TACHYARRHYTHMIAS

In the advanced life support setting, arrhythmias are most usefully classified according to the observed heart rate (slow or fast) and its effect on perfusion (adequate or poor). If, in the primary survey, a caregiver finds a child with an abnormal heart rate plus poor perfusion and/or altered mental status, then the rhythm is inadequate no matter its rate. In those settings, the child is diagnosed with shock, and further evaluation is halted until appropriate resuscitation has been initiated.

Bradyarrhythmias

By definition, a child is *bradycardic* when the heart rate is slower than the normal range for age (see Table 67-1). Sinus bradycardia can be a harmless incidental finding in an otherwise healthy person and is not commonly associated with cardiac compromise. A relative bradycardia occurs when the heart rate is too slow for a child's activity level or metabolic needs. A clinically significant bradycardia occurs when the heart rate is slow and there are signs of systemic hypoperfusion (i.e., pallor, altered mental status, hypotension, acidosis). Symptomatic bradycardia occurs most often in the setting of hypoxia but can also be caused by hypoglycemia, hypocalcemia, other electrolyte abnormalities, and intracranial hypertension. Bradyarrhythmias are often the most common prearrest rhythms in young children.

Initial management of symptomatic bradycardia includes support or opening of the airway and confirming or establishing adequate oxygenation and ventilation (Fig. 67-12). After the child's breathing has been secured, the child should be reassessed for continued bradycardia and poor perfusion. If cardiac compromise was solely the result of respiratory insufficiency, support of the child's airway and breathing may have been sufficient to restore normal hemodynamics. If respiratory support does not correct the perfusion abnormalities, then further care is based on the quality of perfusion and the degree of

Table 67-4 Rapid Sequence Intubation

STEP	PROCEDURE	COMMENT/EXPLANATION
1	Obtain a brief history and perform an assessment	Rule out drug allergies; examine the airway anatomy (e.g., micrognathia, cleft palate)
2	Assemble equipment, medications, etc.	See lists below
3	Preoxygenate the patient	With bag/mask, nasal cannula, hood or blow-by
4	Premedicate the patient with lidocaine, atropine	Lidocaine minimizes the ICP rise with intubation and can be applied topically to the airway mucosa for local anesthesia Atropine helps blunt the bradycardia associated with upper airway manipulation and reduces airway secretions
5	Induce sedation and analgesia	Sedatives: *Thiopental* (2-5 mg/kg): Very rapid onset; can cause hypotension *Diazepam* (0.1 mg/kg): Onset 2-5 min; elimination in 30-60 min or more *Ketamine* (2 mg/kg): Onset 1-2 min; elimination in 30-40 min. May cause hallucinations if used alone; causes higher ICP, mucous secretions, increased vital signs, and bronchodilation Analgesics: *Fentanyl* (3-10 μg/kg, may repeat 3-4×): Rapid administration risks "tight chest" response, with no effective ventilation. Effects wear off in 20-30 min *Morphine* (0.05-0.1 mg/kg dose): May last 30-60 min; may lead to hypotension in hypovolemic patients
6	Pretreat with nondepolarizing paralytic agent	Small dose of a nondepolarizing paralytic agent (see below), with intent of diminishing the depolarizing effect of succinylcholine, which is administered next
7	Administer muscle relaxants	Succinylcholine dose is 1-2 mg/kg; causes initial contraction of muscles, then relaxation. This depolarization can, however, raise ICP and blood pressure. Onset of paralysis in 30-40 sec; duration is 5-10 min Increased use of pretreatment with a nondepolarizing muscle relaxant, especially rocuronium (1 mg/kg), which has a very rapid onset and short duration. Other nondepolarizing agents include vecuronium and pancuronium, both dosed at 0.1 mg/kg
8	Perform a Sellick maneuver	Pressure on the cricoid cartilage, to occlude the esophagus and prevent regurgitation or aspiration
9	Perform endotracheal intubation	ET: Select the proper size for the age and weight of the child Laryngoscope blades: A variety of Miller and the Macintosh blades Patient supine; the neck is extended moderately to the "sniffing" position
10	Secure the tube and verify the position with a roentgenogram	ET secured with tape to the cheeks and upper lip or to an adhesive patch applied to the skin near the mouth
11	Begin mechanical ventilation	Verify tube placement before ventilating with positive pressure; if an ET tube is in one bronchus, barotraumas may occur

ET, endotracheal tube; ICP, intracranial pressure.

bradycardia. **A heart rate less than 60 beats/min with poor perfusion is an indication to begin chest compressions.** If the bradycardia persists, vascular access should be obtained; resuscitative epinephrine should be administered, and it should be repeated every 3-5 min for persistent symptomatic bradycardia. If increased vagal tone (e.g., in the setting of head injury with raised intracranial pressure) or primary atrioventricular block is suspected, atropine can also be given. For cases of refractory bradycardia, cardiac pacing should be considered. During the resuscitation of a child with bradycardia, providers should assess and treat factors known to cause bradycardia, referred to collectively as the **6 Hs** (hypoxia, hypovolemia, hydrogen ions [acidosis], hypokalemia or hyperkalemia, hypoglycemia, hypothermia), and **5 Ts** (toxins, tamponade, tension pneumothorax, thrombosis [in either the pulmonary or cardiac circulations], and trauma [causing hypovolemia, intracranial hypertension, cardiac compromise or tamponade]) (Table 67-5).

Tachyarrhythmias

Tachyarrhythmias represent a variety of rhythm disturbances of both atrial and ventricular origin (see Chapter 435). Sinus tachycardia is a normal physiologic response to the body's need for increased cardiac output or oxygen delivery, as occurs with fever, exercise, or stress. It can also occur in more pathologic states, such as hypovolemia, anemia, pain, anxiety, and metabolic stress. Tachyarrhythmias that do not originate in the sinus node are often categorized as narrow complex rhythms (those originating in the atrium, such as atrial flutter or supraventricular tachycardia [SVT]) and wide complex rhythms (those rhythms of ventricular origin, such as ventricular tachycardia).

The initial management of tachycardia includes confirmation that the child has an adequate airway and life-sustaining breathing and circulation (Fig. 67-13). For children with persistent symptoms, further treatment is based on whether the QRS complex of the electrocardiogram (ECG) is narrow (≤0.09 sec) or wide (>0.09 sec). For narrow complex tachycardia, providers must distinguish between sinus tachycardia and SVT. In sinus tachycardia, (a) the history and onset are consistent with a known cause of tachycardia, such as fever or dehydration and (b) P waves are consistently present, are of normal morphology, and occur at a rate that varies somewhat. In SVT, (a) onset is often abrupt without prodrome and (b) P waves are absent or polymorphic, and when present, their rate is often fairly steady at or above 220 beats/min. For children with SVT and good perfusion, vagal maneuvers can be attempted. In cases in which SVT is associated with poor perfusion, providers should rapidly move to convert the child's heart rhythm back to sinus rhythm. If the child already has IV access, then adenosine can be given via IV with rapid "push." Adenosine has an extremely short half-life, so a proximal IV is best, and the adenosine should be set up with a 3-way stopcock so it can be given and immediately flushed into the circulation. If the child does not have IV access, or adenosine does

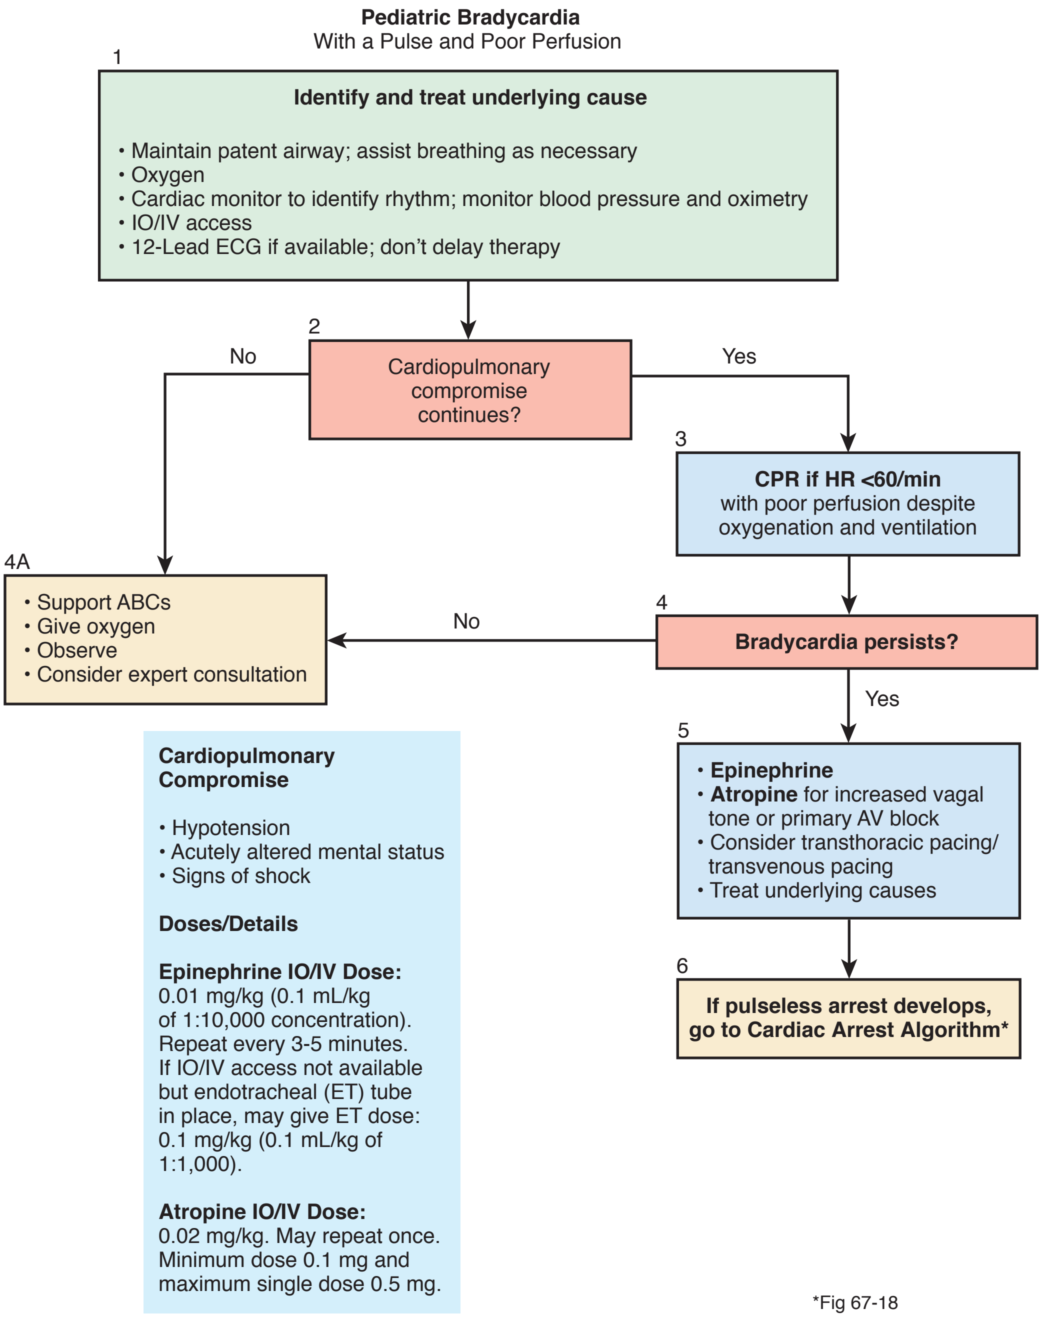

Figure 67-12 Pediatric advanced life support bradycardia algorithm. ABCs, airway, breathing, and circulation; AV, atrioventricular (conductor); ECG, electrocardiogram; HR, heart rate. *(From Kleinman ME, Chameides L, Schexnayder SM, et al: 2010 American Heart Association guidelines for cardiopulmonary resuscitation and emergency cardiovascular care, part 14,* Circulation *122[Suppl 3]:S876–S908, 2010, Fig. 2, p. S887.)*

not successfully convert the heart rhythm back to sinus rhythm, then **synchronized cardioversion**, using 0.5-1.0 joule/kg, should be performed. In cases of wide complex tachycardia, providers should move immediately to cardioversion and increase the dose to 2 joules/kg if 1 joule/kg is not effective. As with cases of bradycardia, providers should review the 6 Hs and 5 Ts to identify factors that might be contributing to the tachycardia (see Table 67-5).

RECOGNITION AND MANAGEMENT OF CARDIAC ARREST

Cardiac arrest occurs when the heart fails as an effective pump and blood flow ceases. Outwardly, the patient in cardiac arrest presents as unresponsive and apneic with no palpable pulse. Internally, the cessation of nutrient flow causes progressive tissue ischemia and organ dysfunction. If not rapidly reversed, cardiac arrest leads to progressive deterioration in brain and heart function such that resuscitation and recovery are no longer possible.

Pediatric cardiac arrest is rarely caused by a sudden coronary event or arrhythmia. Instead, cardiac arrest in children is most often the end result of progressive asphyxia, caused by tissue hypoxia, acidosis, and nutrient depletion at the end stages of respiratory deterioration, shock, or heart failure. Therefore, **the most important treatment of cardiac arrest is anticipation and preventive: Intervening when a child manifests respiratory distress or early stages of shock can prevent deterioration to full-blown arrest**. When sudden cardiac arrest does occur, it is most often associated with an arrhythmia, specifically ventricular fibrillation (VF) or pulseless ventricular tachycardia (VT). In sudden events such as these, the key to successful resuscitation is early

Table 67-5 Potentially Treatable Conditions Associated with Cardiac Arrest

CONDITION	COMMON CLINICAL SETTINGS	CORRECTIVE ACTIONS
Acidosis	Preexisting acidosis, diabetes, diarrhea, drugs and toxins, prolonged resuscitation, renal disease, and shock	Reassess the adequacy of cardiopulmonary resuscitation, oxygenation, and ventilation; reconfirm endotracheal tube placement Hyperventilate Consider intravenous bicarbonate if pH <7.2 after above actions have been taken
Cardiac tamponade	Hemorrhagic diathesis, cancer, pericarditis, trauma, after cardiac surgery, and after myocardial infarction	Administer fluids; obtain bedside echocardiogram, if available Perform pericardiocentesis; immediate surgical intervention is appropriate if pericardiocentesis is unhelpful but cardiac tamponade is known or highly suspected
Hypothermia	Alcohol abuse, burns, central nervous system disease, debilitated patient, drowning, drugs and toxins, endocrine disease, history of exposure, homelessness, extensive skin disease, spinal cord disease, and trauma	If hypothermia is severe (temperature <30°C [86°F]), limit initial shocks for ventricular fibrillation or pulseless ventricular tachycardia to 3; initiate active internal rewarming and cardiopulmonary support If hypothermia is moderate (temperature 30-34°C [86-93.2°F]), proceed with resuscitation (space medications at longer intervals than usual), passively rewarm child, and actively rewarm truncal body areas
Hypovolemia, hemorrhage, anemia	Major burns, diabetes, gastrointestinal losses, hemorrhage, hemorrhagic diathesis, cancer, pregnancy, shock, and trauma	Administer fluids Transfuse packed red blood cells if hemorrhage or profound anemia is present Thoracotomy is appropriate when a patient has cardiac arrest from penetrating trauma and a cardiac rhythm and the duration of cardiopulmonary resuscitation before thoracotomy is <10 min
Hypoxia	Consider in all patients with cardiac arrest	Reassess the technical quality of cardiopulmonary resuscitation, oxygenation, and ventilation; reconfirm endotracheal tube placement
Hypomagnesemia	Alcohol abuse, burns, diabetic ketoacidosis, severe diarrhea, diuretics, and drugs (e.g., cisplatin, cyclosporine, pentamidine)	Administer 1-2 g magnesium sulfate IV over 2 min
Poisoning	Alcohol abuse, bizarre or puzzling behavioral or metabolic presentation, classic toxicologic syndrome, occupational or industrial exposure, and psychiatric disease	Consult a toxicologist for emergency advice on resuscitation and definitive care, including an appropriate antidote Prolonged resuscitation efforts may be appropriate; immediate cardiopulmonary bypass should be considered, if available
Hyperkalemia	Metabolic acidosis, excessive administration of potassium, drugs and toxins, vigorous exercise, hemolysis, renal disease, rhabdomyolysis, tumor lysis syndrome, and clinically significant tissue injury	If hyperkalemia is identified or strongly suspected, treat* with all of the following: 10% calcium chloride (5-10 mL by slow IV push; do not use if hyperkalemia is secondary to digitalis poisoning), glucose and insulin (50 mL of 50% dextrose in water and 10 units of regular insulin IV), sodium bicarbonate (50 mmol IV; most effective if concomitant metabolic acidosis is present), and albuterol (15-20 mg nebulized or 0.5 mg by IV infusion)
Hypokalemia	Alcohol abuse, diabetes, use of diuretics, drugs and toxins, profound gastrointestinal losses, hypomagnesemia	If profound hypokalemia (<2.0-2.5 mmol of potassium) is accompanied by cardiac arrest, initiate urgent IV replacement (2 mmol/min IV for 10-15 mmol)*; then reassess
Pulmonary embolism	Hospitalized patient, recent surgical procedure, peripartum, known risk factors for venous thromboembolism, history of venous thromboembolism, or prearrest presentation consistent with a diagnosis of acute pulmonary embolism	Administer fluids; augment with vasopressors as necessary Confirm the diagnosis, if possible; consider immediate cardiopulmonary bypass to maintain patient's viability Consider definitive care (e.g., thrombolytic therapy, embolectomy by interventional radiology or surgery)
Tension pneumothorax	Placement of a central catheter, mechanical ventilation, pulmonary disease (including asthma, chronic obstructive pulmonary disease, and necrotizing pneumonia), thoracentesis, and trauma	Needle decompression, followed by chest tube insertion

*Adult dose. Adjust for size of child. See Table 67-6.

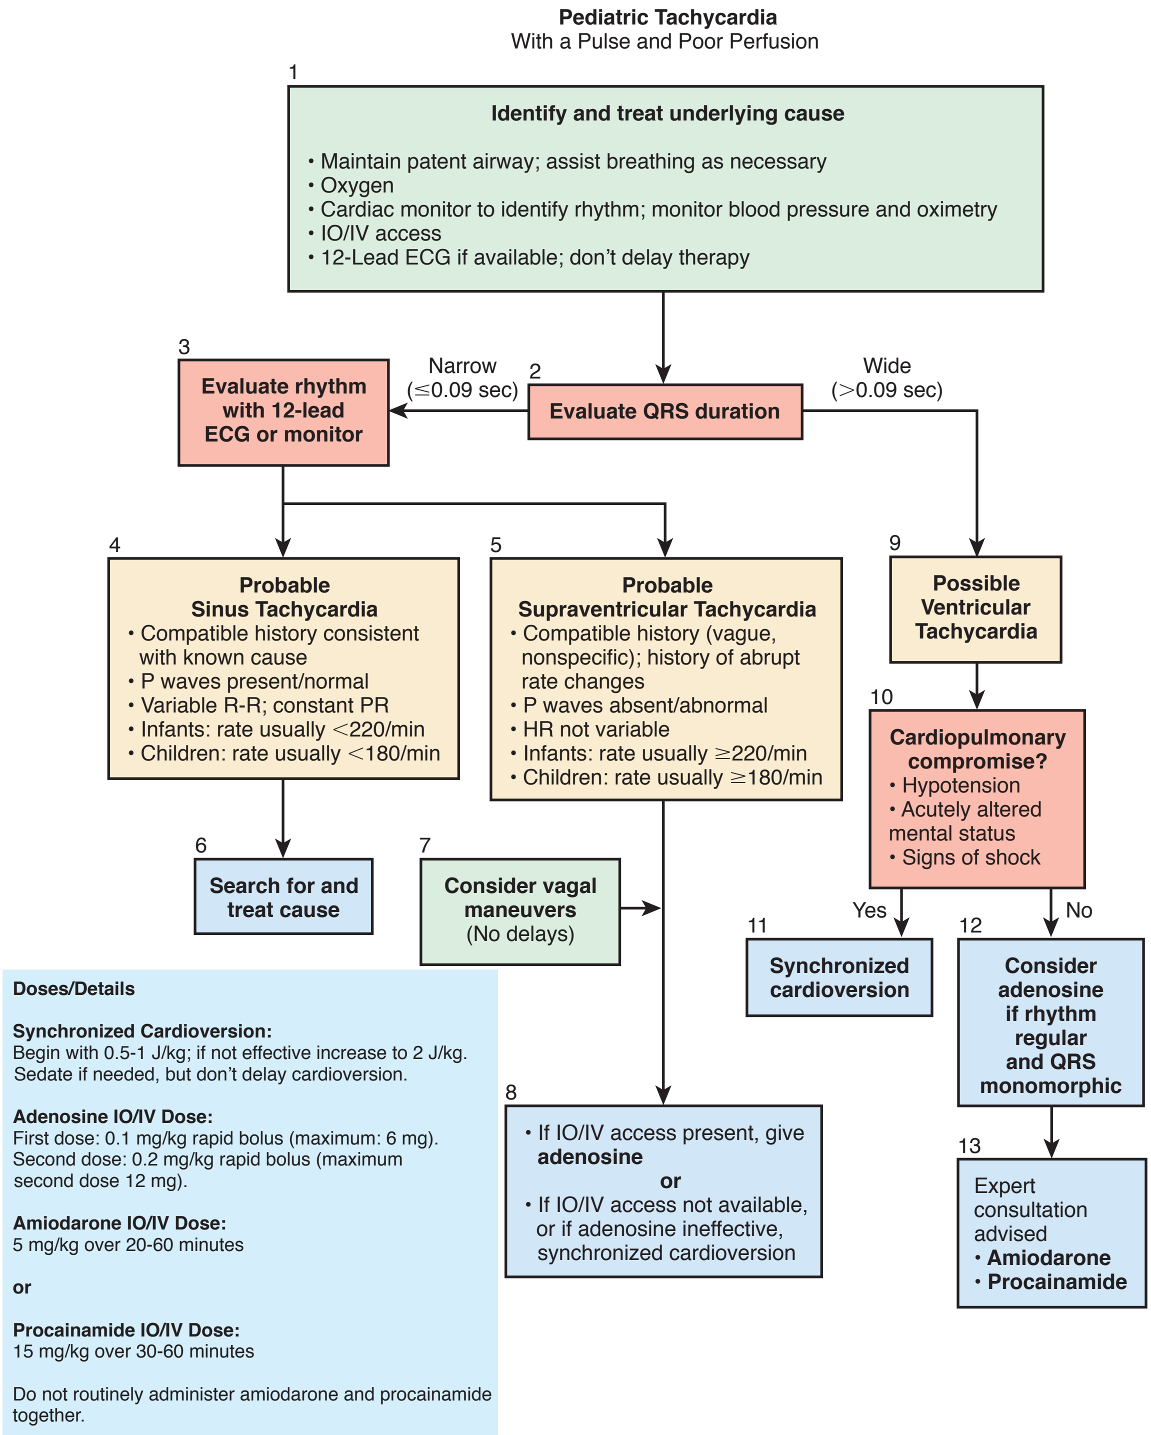

Figure 67-13 **Pediatric advanced life support tachycardia algorithm.** AV, atrioventricular (conductor); ECG, electrocardiogram; HR, heart rate. *(From Kleinman ME, Chameides L, Schexnayder SM, et al: 2010 American Heart Association guidelines for cardiopulmonary resuscitation and emergency cardiovascular care, part 14,* Circulation *122[Suppl 3]:S876–S908, 2010, Fig. 3, p. S888.)*

recognition of the arrhythmia and prompt treatment with high-quality CPR and defibrillation.

The principle behind high-quality CPR is that adequate chest compressions—those that circulate blood around the body with a good pulse pressure—are the most important component of CPR. The caregiver providing chest compressions should ***push hard, push fast, allow for complete chest recoil, and minimize interruptions.*** Ideally, chest compressions should be interrupted only for ventilation, a rhythm check, or delivery of a defibrillating shock.

Cardiac arrest is recognized from general and primary survey findings consistent with a pale or cyanotic child who is unresponsive, apneic, and pulseless. Even experienced providers have a relatively high error rate when asked to determine presence or absence of pulse in a child. Therefore, any child found unresponsive and apneic can be presumed to be in cardiac arrest, and a rescuer should respond accordingly. **A lone rescuer for an *unwitnessed* pediatric cardiac arrest in an outpatient setting should treat the arrest as asphyxial in nature and should immediately initiate CPR.** The rescuer should perform

Figure 67-14 Combined jaw-thrust/spine stabilization maneuver for the pediatric trauma victim. *(From Guidelines for cardiopulmonary resuscitation and emergency cardiac care. Emergency Cardiac Care Committee and Subcommittees, American Heart Association. Part V. Pediatric basic life support,* JAMA *268:2251–2261, 1992.)*

initial rescue breaths and 2 min of chest compressions and ventilations before leaving the child to activate the emergency response system. For an in-hospital arrest, the provider should call for help and send someone else to activate the emergency response system while beginning CPR. **A lone rescuer in an outpatient setting who *witnesses* a child's sudden collapse should treat the arrest as a primary arrhythmia, should immediately activate the EMS system, and should obtain an AED.** Upon returning to the child, the rescuer should confirm pulselessness, turn on the AED, place the leads on the child's chest, and follow the defibrillator's voice commands.

The initial step in CPR for a child of any age is to restore ventilation and oxygenation as quickly as possible. Upon confirmation of unresponsiveness, apnea, and pulselessness, the provider should open the airway with a head-tilt/chin-lift maneuver (or jaw-thrust if cervical spine trauma is suspected) and provide 2 initial rescue breaths (Fig. 67-14). These breaths are deep and slow, lasting approximately 1 sec per breath. The breaths are adequate if they cause the chest to rise and fall and improve the child's color. If the breaths appear inadequate, the child should be repositioned, and the breaths delivered again. If the breaths remain ineffective, the provider should assess the child for foreign body aspiration. After 2 effective rescue breaths, the child's pulse should be assessed. If the child has a pulse but remains apneic (or with ineffective breathing), then the rescuer should continue to provide assisted ventilation at an age-appropriate rate. Infants and children ≤8 yr old should receive rescue breathing at a rate of roughly 15-20 breaths/min, or roughly 1 breath every 3-5 sec. Children >8 yr old should receive 10-12 breaths/min, or 1 breath every 5-6 sec.

If the child remains pulseless, chest compressions should be initiated. Chest compressions in infants <1 yr old may be performed by placing 2 thumbs on the midsternum with the hands encircling the thorax or by placing 2 fingers over the midsternum and compressing (Figs. 67-15 and 67-16). For children >1 yr old, the care provider should perform chest compressions over the lower half of the sternum with the heel of 1 hand, or with 2 hands as used for adult resuscitation (Fig. 67-17). In all cases, care should be taken to avoid compression of the xiphoid and the ribs. When feasible, a cardiac resuscitation board should be placed under the child's back to maximize the efficiency of compressions. When a lone rescuer provides CPR, the universal ratio of 30 compressions to 2 ventilations is used. Pediatric patients in cardiac arrest are thought to have the best chance of survival if more frequent ventilation is offered. Therefore, the ratio should be lowered to 15 compressions to 2 ventilations for children ≤8 yr old as soon as a second care provider is available. In the outpatient setting, resuscitation effort should pause periodically to allow the provider to make an assessment of the possible return of spontaneous heart rate, pulse, and respirations. The goal of CPR is to reestablish spontaneous circulation

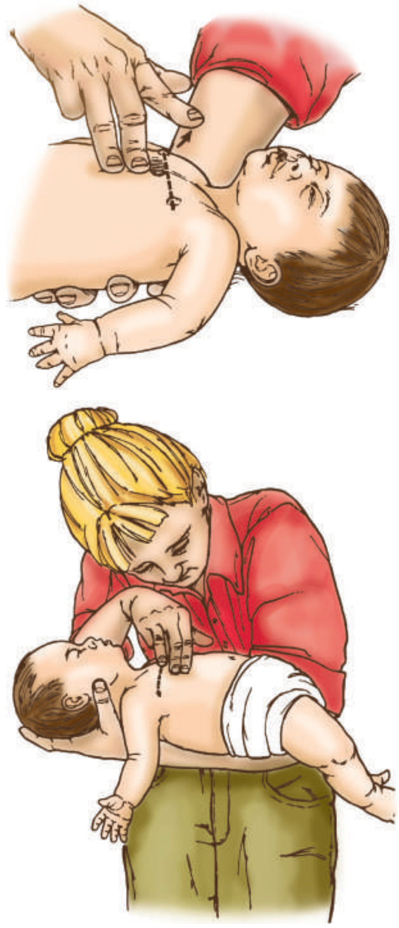

Figure 67-15 Cardiac compressions. *Top,* The infant is supine on the palm of the rescuer's hand. *Bottom,* Performing CPR while carrying an infant or small child. Note that the head is kept level with the torso. *(From Guidelines for cardiopulmonary resuscitation and emergency cardiac care. Emergency Cardiac Care Committee and Subcommittees, American Heart Association. Part V. Pediatric basic life support,* JAMA *268:2251–2261, 1992.)*

at a level that is compatible with survival. If resuscitative efforts do not succeed in reestablishing life-sustaining breathing and circulation, the medical team must decide whether continued efforts are warranted or whether the resuscitation should be stopped. If EMS care is en route, bringing the potential for further escalation in care such as endotracheal intubation, vascular access, and medications, CPR should be continued as long as possible or deemed reasonable by the rescuers.

In the in-hospital setting, the ECG should dictate further resuscitative efforts. For children without a pulse and in asystole or electromechanical dissociation (pulseless electrical activity), providers should continue rescue breathing and CPR, obtain vascular access, and give emergency IV epinephrine (Fig. 67-18). For continued asystole or pulseless electrical activity, epinephrine can be repeated every 3-5 min. Patient history, physical exam findings, and laboratory evaluation should be used to elicit correctable causes of arrest (such as the 6 Hs and 5 Ts) (see Table 67-5). CPR should be continued after epinephrine administration, to circulate the drug through the body. After 5 cycles of CPR, providers should reassess the child for the presence of a pulse or a change in the ECG rhythm that would necessitate a different response.

For those children with pulseless VT or VF, emergency defibrillation is indicated (see Fig. 67-18). Providers should apply the pads to the child's bare chest and back and follow the verbal instructions given by the AED. For younger children, a defibrillator (if available) set to the dose of 2 joules/kg should be used. Ideally, the AED used in a child

Thumbs are side by side over the lower third of the sternum. In the small newborn, thumbs may need to be superimposed *(inset)*. Gloves should be worn during resuscitation. *(From Fleisher GR, Ludwig S, editors:* Textbook of pediatric emergency medicine, *Philadelphia, 2010, Wolters Kluwer/Lippincott Williams & Wilkins Health, Fig. 2.2.)*

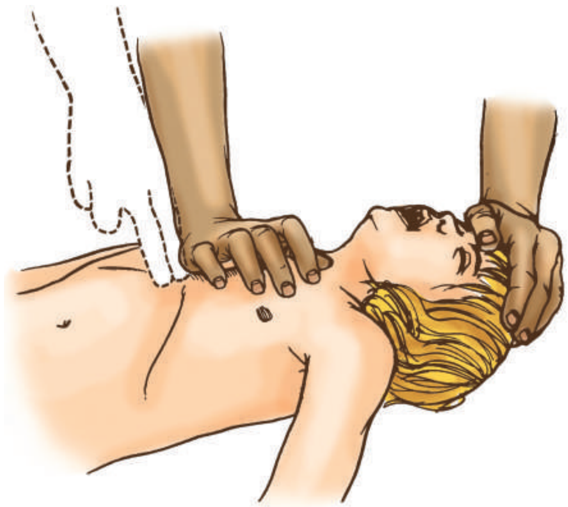

Figure 67-17 **Locating the hand position for chest compression in a child.** Note that the rescuer's other hand is used to maintain the head position to facilitate ventilation. *(From Guidelines for cardiopulmonary resuscitation and emergency cardiac care. Emergency Cardiac Care Committee and Subcommittees, American Heart Association. Part V. Pediatric basic life support,* JAMA *268:2251–2261, 1992.)*

≤8 yr of age should be equipped with an attenuated adult dose or should be designed for children; if neither device is available, a standard adult AED should be used. CPR should be immediately restarted after defibrillation. Emergency dose epinephrine can also be administered with another 5 cycles of CPR to ensure its circulation throughout the child's body. If the ECG rhythm continues to show VF or VT, defibrillation can be alternated with epinephrine. For refractory VF or VT, an IV antiarrhythmic, such as amiodarone or lidocaine, can be given (Tables 67-6 and 67-7).

New approaches to CPR in adults have highlighted the potential value of bystander chest compression alone in the initial resuscitation in a community setting. In addition, the combination of vasopressin, methylprednisolone, and epinephrine during an in-hospital cardiac arrest followed by hydrocortisone during the postresuscitation shock period has resulted in a better outcome than patients treated with epinephrine alone. Whether these observations are applicable to young children, who often have different etiologies for cardiopulmonary arrest, has not been determined.

Traditionally, continuing CPR >20 min in children with in-hospital cardiac arrest has been considered futile. With current practice for CPR, survival for in-hospital cardiac arrest is approximately 40% for CPR duration <15 min compared with approximately 12% for CPR lasting >35 min. Survivors had a favorable neurologic outcome in 70% with a CPR duration <15 min compared with 60% for those requiring resuscitation for >35 min.

VASCULAR ACCESS

Venous Access

Veins suitable for cannulation are numerous, but there is considerable anatomic variation from patient to patient. In the upper extremities, the median antecubital vein, located in the antecubital fossa, is often the largest and easiest to access (Fig. 67-19). Many veins on the dorsum of the hand are also suitable for cannulation because they are often large and easily located on the flat surface of the dorsum of the hand, and their cannulation is well tolerated. The cephalic vein is usually cannulated at the wrist, along the forearm, or at the elbow. The median vein of the forearm is also suitable because it lies along a flat surface of the forearm. In the lower extremity, the great saphenous vein, located just anterior to the medial malleolus, is accessible in most patients. The dorsum of the foot usually has a large vein in the midline, passing across the ankle joint, but catheters are difficult to maintain in this vein because dorsiflexion tends to dislodge them. A second large vein on the lateral side of the foot, running in the horizontal plane, usually 1-2 cm dorsal to the lower margin of the foot, is preferable (Fig. 67-20). The most notable scalp veins are the superficial temporal (just anterior to the ear) and posterior auricular (just behind the ear).

Deeper and larger central veins can provide more reliable, larger-bore access for medications, nutritive solutions, and blood sampling than peripheral venous lines. They may be reached by percutaneous cannulation or surgical exposure. In infants and young children, the femoral vein is often the easiest to access and cannulate, but the internal jugular and subclavian veins may also be used (Figs. 67-21 and 67-22). Because of its proximity to the median nerve, the brachial vein is not often recommended for cannulation.

Intraosseous Access

Intraosseous (IO) needles (for intramedullary venous plexus access) are special rigid, large-bore needles that resemble those used for bone marrow aspiration. IO cannulation is recommended for patients for whom IV access proves difficult or unattainable, even in older children. If venous access is not available within 1 min in a child with cardiopulmonary arrest, an IO needle should be placed in the anterior proximal tibia (with care taken to avoid traversing the epiphyseal plate). The needle should penetrate the anterior layer of compact bone, and its tip

S885.)*

Table 67-6 Medications for Pediatric Resuscitation and Arrhythmias

MEDICATION	DOSE	REMARKS
Adenosine	0.1 mg/kg (maximum 6 mg) Repeat: 0.2 mg/kg (maximum 12 mg)	Monitor ECG Rapid IV/IO bolus
Amiodarone	5 mg/kg IV/IO; repeat up to 15 mg/kg Maximum: 300 mg	Monitor ECG and blood pressure Adjust administration rate to urgency (give more slowly when perfusing rhythm is present) Use caution when administering with other drugs that prolong QT interval (consider expert consultation)
Atropine	0.02 mg/kg IV/IO 0.03 mg/kg ET* Repeat once if needed Minimum dose: 0.1 mg Minimum single dose: Child, 0.5 mg Adolescent, 1 mg	Higher doses may be used with organophosphate poisoning
Calcium chloride (10%)	20 mg/kg IV/IO (0.2 mL/kg)	Slowly Adult dose: 5-10 mL
Epinephrine	0.01 mg/kg (0.1 mL/kg 1 : 10,000) IV/IO 0.1 mg/kg (0.1 mL/kg 1 : 1,000) ET* Maximum dose: 1 mg IV/IO; 10 mg ET	May repeat q 3-5 min
Glucose	0.5-1 g/kg IV/IO	D10W: 5-10 mL/kg D25W: 2-4 mL/kg D50W: 1-2 mL/kg
Lidocaine	Bolus: 1 mg/kg IV/IO Maximum dose: 100 mg Infusion: 20-50 μg/kg/min ET*: 2-3 mg	
Magnesium sulfate	25-50 mg/kg IV/IO over 10-20 min; faster in torsades de pointes Maximum dose: 2g	
Naloxone	<5 yr or ≤20 kg: 0.1 mg/kg IV/IO/ET* ≥5 yr or >20 kg: 2 mg IV/IO/ET*	Use lower doses to reverse respiratory depression associated with therapeutic opioid use (1-15 μg/kg)
Procainamide	15 mg/kg IV/IO over 30-60 min Adult dose: 20 mg/min IV infusion up to total maximum dose of 17 mg/kg	Monitor EGG and blood pressure Use caution when administering with other drugs that prolong QT interval (consider expert consultation)
Sodium bicarbonate	1 mEq/kg/dose IV/IO slowly	After adequate ventilation

*Flush with 5 mL of normal saline and follow with 5 ventilations.
ECG, electrocardiogram; ET, endotracheal tube; IO, intraosseous; IV, intravenous.

advanced into the spongy interior of the bone (Fig. 67-23). Commercially available IO kits frequently include drills that obviate the complications of needle placement associated with manual placement. Any and all medications, blood products, and fluids may be administered through the IO route, including all medications required for emergency resuscitation. Complications are uncommon, but may include osteomyelitis with prolonged infusions and tibial fracture.

Arterial Access

Arterial access is indicated when care providers need frequent blood sampling, particularly to assess adequacy of oxygenation, ventilation, or acid–base balance, and/or continuous blood pressure monitoring. The radial artery, the most commonly cannulated artery, lies on the lateral side of the anterior wrist, just medial to the styloid process of the radius (Fig. 67-24). The ulnar artery, just lateral to the tendon of the flexor carpi ulnaris, is used less often because of its proximity to the ulnar nerve. Useful sites in the lower extremity, particularly in neonates and infants, are the dorsalis pedis artery, on the dorsum of the foot between the tendons of the tibialis anterior and the extensor hallucis longus, and the posterior tibial artery, posterior to the medial

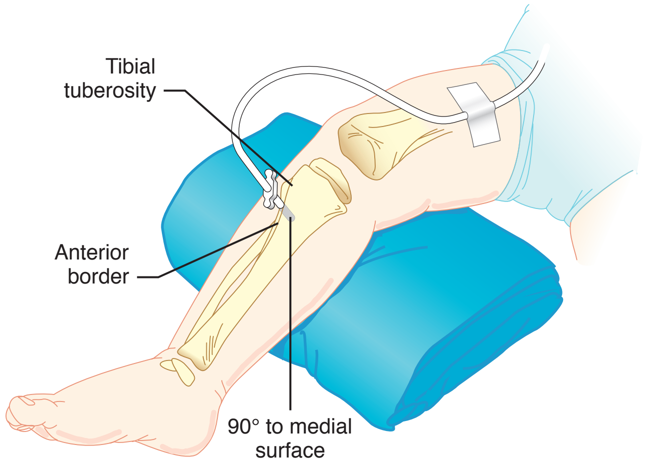

Figure 67-23 Intraosseous cannulation technique. *(From Zwass MS, Gregory GA: Pediatric and neonatal intensive care. In Miller RD, Eriksson LI, Fleisher LA, et al, editors:* Miller's anesthesia, *ed 7, Philadelphia, 2009, Churchill Livingstone, Fig. 84-1.)*

malleolus. Arterial catheters require special care for insertion and subsequent management because the blood flow to tissue can be compromised and considerable hemorrhage can occur if an arterial catheter is dislodged.

NONVASCULAR EMERGENCY PROCEDURES

Thoracentesis and Chest Tube Placement

Thoracentesis is the placement of a needle or catheter into the pleural space to evacuate fluid, blood, or air. Most insertions are performed in one of the intercostal spaces between the 4th and 9th ribs in the plane of the midaxillary line. After appropriate systemic and local anesthesia/sedation is performed as clinically indicated, a skin incision is made, and dissection through the chest wall is accomplished in layers with use of blunt dissection techniques. The needle (and later, the chest tube) that enters the pleural space should penetrate the intercostal space by passing over the superior edge of the lower rib, because there are larger vessels along the inferior edge of the rib. Ideally, the chest tube should lie anterior in the pleural space for air accumulation, and posterior for fluid accumulation. A radiograph must be obtained to verify chest tube placement and evacuation of the pleural space.

Pericardiocentesis

When fluid, blood, or gas accumulates in the pericardial sac, a danger is that the heart will be compressed and will not be able to fill and empty with normal volumes of blood, leading to diminished cardiac output. The cardinal signs of such a restrictive pericardial effusion are tachycardia, hypotension, and decreasing oxygen saturation. Pericardiocentesis includes needle aspiration of the pericardial sac, often followed by the placement of a catheter for continuous drainage. As for thoracentesis, chest radiography should be done to confirm catheter location as well as to evaluate for presence of any complications, such as pneumothorax or hemothorax.

POSTRESUSCITATION CARE

After successful resuscitation, close observation in an intensive care unit, where the child can receive ongoing multiorgan system assessments and support, is critical. Optimal postresuscitation care includes ongoing support of cardiovascular and respiratory system function as needed and the identification and treatment of other organ system dysfunction that may have contributed to (or resulted from) the child's cardiopulmonary instability. Good postresuscitation intensive care also includes supportive services for the child's parents, siblings, family, and friends.

Induced hypothermia (32-34°C [89.6-91.4°F] for ≈48 hr) may improve survival and neurologic function in adult and pediatric survivors of CPR. This is a controversial treatment that has inconsistently proven beneficial in comatose adult survivors of cardiac arrest. Randomized clinical trials in children are in progress. *Furthermore, hyperthermia must be avoided.* Hypoxic-ischemic encephalopathy with subsequent development of seizures, intellectual impairment, and spasticity, is a serious and common complication of cardiac arrest. *In addition hyperglycemia and hypoglycemia should be avoided.*

Postresuscitation management generally has 2 phases, similar to earlier, emergency resuscitative care. First, the providers must assess the child's airway and breathing and must support oxygenation and ventilation as indicated. If the child has ongoing respiratory failure and has been supported with bag-valve-mask ventilation until this time, the providers should now move forward with intubation. Once the child is intubated, mechanical ventilation must be established, and respiratory assessments performed, such as chest radiography and arterial blood gas sampling and analysis. The child's circulatory system must also be assessed and supported as needed. Continuous arterial blood pressure monitoring can help the provider determine the need for, and response to, inotropic and chronotropic medications (see Table 67-7). Once the ABCs have been managed, providers can move on to full organ system assessments. A systematic approach that employs a full physical exam and laboratory evaluation to reveal the child's respiratory, cardiovascular, neurologic, gastrointestinal, renal, and hematologic system function should be used.

Communication with the family is an essential element of postresuscitation care. The family should be thoroughly briefed on the elements of the resuscitation performed, the child's condition, and ongoing medical concerns, uncertainties, or issues by the *most senior provider available*. This provider should be available to answer the family's questions, clarify information, and provide comfort. Other support staff, such as social workers and chaplains, should be contacted, as the family wishes, to provide additional support and comfort. For situations in which the resuscitation is ongoing and the child is not expected to survive, the American Academy of Pediatrics recommends that the provider make every effort possible to have the family present at the bedside if they wish. Family presence during CPR or other emergency resuscitative efforts, even if the child dies, is associated with a more positive medical experience than if they are excluded. In cases in which the child is critically ill but stable, the family should be brought to the bedside as soon as the healthcare team deems it safe and appropriate.

Chapter 68

Neurologic Emergencies and Stabilization

Patrick M. Kochanek and Michael J. Bell

NEUROCRITICAL CARE PRINCIPLES

The brain has high metabolic demands, which are further increased during growth and development. Preservation of nutrient supply to the brain is the mainstay of care for children with evolving brain injuries. *Intracranial dynamics* describes the physics of the interactions of the contents—brain parenchyma, blood (arterial, venous, capillary) and cerebrospinal fluid (CSF)—within the cranium. Normally, brain parenchyma accounts for up to 85% of the contents of the cranial vault, and the remaining portion is divided between CSF and blood. The brain resides in a relatively rigid cranial vault, and cranial compliance decreases with age as the skull ossification centers gradually replace cartilage with bone. The **intracranial pressure (ICP)** is derived from the volume of its components and the bony compliance. The **perfusion pressure** of the brain (cerebral perfusion pressure [CPP]) is equal to the pressure of blood entering the cranium (mean arterial pressure) minus the ICP, in most cases.

Increases in intracranial volume can result from swelling, masses, or increases in blood and CSF volumes. As these volumes increase, compensatory mechanisms decrease ICP by (a) decreasing CSF volume (CSF is displaced into the spinal canal or absorbed by arachnoid villi), (b) decreasing cerebral blood volume (venous blood return to the thorax is augmented), and/or (c) increasing cranial volume (sutures pathologically expand or bone is remodeled). Once compensatory mechanisms are exhausted (the increase in cranial volume is too large), small increases in volume lead to large increases in ICP or intracranial hypertension (Fig. 68-1). As ICP continues to increase, brain ischemia can occur as CPP falls. Further increases in ICP can ultimately displace the brain downward into the foramen magnum—a process called **cerebral herniation,** which can become irreversible in minutes and may lead to severe disability or death; Figure 68-2 notes other sites of brain herniation.

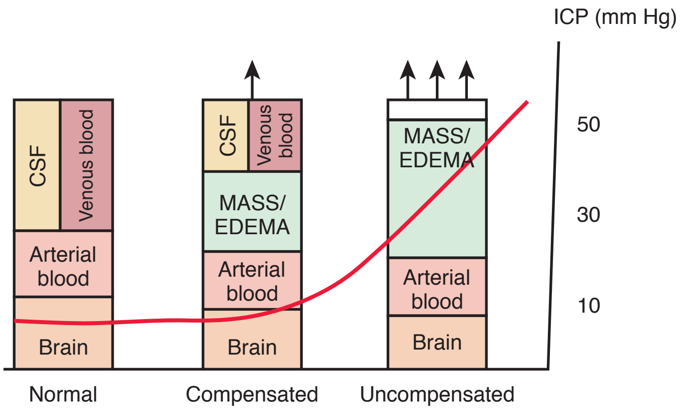

Figure 68-1 The Munro-Kellie doctrine describes intracranial dynamics in the setting of an expanding mass lesion (i.e., hemorrhage, tumor) or brain edema. In the normal state, the brain parenchyma, arterial blood, CSF, and venous blood occupy the cranial vault at a low pressure, generally <10 mm Hg. With an expanding mass lesion or brain edema, initially there is a compensated state as a result of reduced CSF and venous blood volumes, and ICP remains low. Further expansion of the lesion, however, leads to an uncompensated state when compensatory mechanisms are exhausted and intracranial hypertension results. See text for details.

Oxygen and glucose are required by brain cells for normal functioning, and these nutrients must be constantly supplied by cerebral blood flow (CBF). Normally, CBF is constant over a wide range of blood pressures (blood pressure autoregulation of CBF) via actions mainly within the cerebral arterioles. Cerebral arterioles are maximally dilated at lower blood pressures and maximally constricted at higher pressures so that CBF does not vary during normal fluctuations (Fig. 68-3). Acid–base balance of the CSF (often reflected by acute changes in arterial partial pressure of carbon dioxide [$Paco_2$]), body/brain temperature, glucose utilization, and other vasoactive mediators (i.e., adenosine, nitric oxide) can also affect the cerebral vasculature.

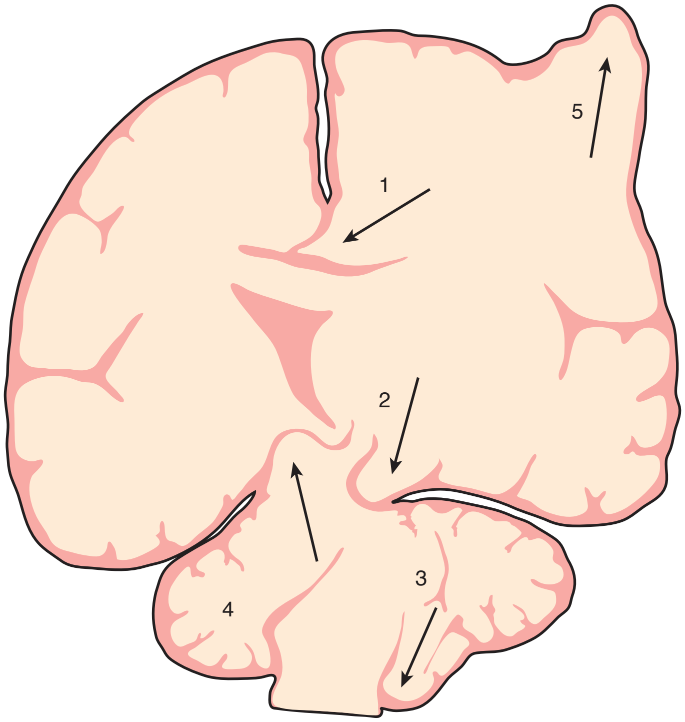

Figure 68-2 Different forms of brain herniation. *1,* Cingulate. *2,* Uncal. *3,* Cerebellar tonsillar. *4,* Upward cerebellar. *5,* Transcalvarial. *(From Fishman RA:* Cerebrospinal fluid in diseases of the nervous system, *Philadelphia, 1980, Saunders.)*

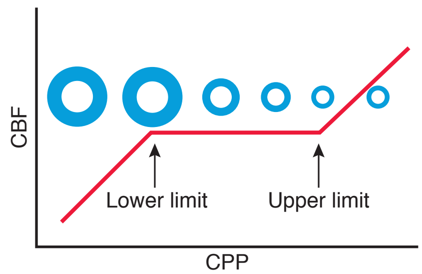

Figure 68-3 Schematic of the relationship between CBF and CPP. The diameter of a representative cerebral arteriole is also shown across the center of the *y* axis to facilitate understanding of the vascular response across CPP that underlies blood pressure autoregulation of CBF. CPP is generally defined as the mean arterial pressure (MAP) minus the ICP. At normal values for ICP, this generally represents MAP. Thus, normally, CBF is kept constant between the lower limit and upper limit of autoregulation; in normal adults, these values are ≈50 mm Hg and 150 mm Hg, respectively. In children, the upper limit of autoregulation is likely proportionally lower than the adult value relative to normal MAP for age. However, according to the work of Vavilala et al. (2003), lower limit values are surprisingly similar in infants and older children. Thus, infants and young children may have less reserve for adequate CPP. See text for details.

Knowledge of these concepts is instrumental to preventing secondary brain injury. Increases in CSF pH that occur because of inadvertent hyperventilation (decreased $Paco_2$) can produce cerebral ischemia. Hyperthermia-mediated increases in cerebral metabolic demands may damage vulnerable brain regions after injury. Hypoglycemia can produce neuronal death when CBF fails to compensate. Prolonged seizures can lead to permanent injuries if hypoxemia occurs from loss of airway control.

Attention to detail and constant reassessment are paramount in managing children with critical neurologic insults. Among the most valuable tools for serial, objective assessments of neurologic condition is the Glasgow Coma Scale (GCS) (see Table 67-3 in Chapter 67). Originally developed to assess level of consciousness after traumatic brain injury (TBI) in adults, the GCS is also valuable in pediatrics. Modifications to the GCS have been made for nonverbal children and are available for infants and toddlers (see Table 67-3 in Chapter 67). Serial assessments of the GCS score along with a focused neurologic examination are invaluable to detection of injuries before permanent damage occurs in the vulnerable brain.

The FOUR (full outline of unresponsiveness) score (Table 68-1) is a modification of the GCS, which eliminates the verbal response but adds two functional assessments of the brain stem (pupil, corneal, cough reflexes, and respiratory patterns).

The most-studied monitoring device in clinical practice is the **ICP monitor**. Monitoring is accomplished by a catheter inserted either into the cerebral ventricle (externalized ventricular drain) or into brain parenchyma (parenchymal transducer). ICP-directed therapies are standard of care in TBI and are used in other conditions, such as intracranial hemorrhage, Reye syndrome, and some cases of encephalopathy, meningitis, and encephalitis. Other devices being used include catheters that measure brain tissue oxygen concentration, external probes that noninvasively assess brain oxygenation by absorbance of near-infrared light (near-infrared spectroscopy), monitors of brain electrical activity (continuous electroencephalography [EEG] or somatosensory, visual, or auditory evoked potentials), and CBF monitors (transcranial Doppler, xenon CT, perfusion MRI, or tissue probes). In the current severe TBI guidelines, brain tissue oxygen concentration monitoring received level III support and thus, may be considered.

TRAUMATIC BRAIN INJURY

Etiology

Mechanisms of TBI include motor vehicle crashes, falls, assaults, and abusive head trauma. Most TBIs in children are from closed-head injuries.

Epidemiology

TBI is an important pediatric public health problem, with approximately 37,000 cases resulting in the death of more than 7,000 children annually in the United States.

Pathology

Epidural, subdural, and parenchymal intracranial hemorrhages can result. Injury to gray or white matter is also commonly seen and includes focal cerebral contusions, diffuse cerebral swelling, axonal injury, and injury to the cerebellum or brainstem. Patients with severe TBI often have multiple findings; diffuse and potentially delayed cerebral swelling is common.

Pathogenesis

TBI results in primary and secondary injury. Primary injury from the impact produces irreversible tissue disruption. In contrast, 2 types of secondary injury are targets of neurointensive care. First, some of the ultimate damage seen in the injured brain evolves over hours or days, and the underlying mechanisms involved (edema, apoptosis, and secondary axotomy) are therapeutic targets. Second, the injured brain is vulnerable to additional insults because injury disrupts normal autoregulatory defense mechanisms; disruption of autoregulation of CBF can lead to ischemia from hypotension that would otherwise be tolerated by the uninjured brain.

Table 68-1 Commonly Used Coma Scores

GLASGOW COMA SCALE	FULL OUTLINE OF UNRESPONSIVENESS (FOUR) SCORE
Eye Opening 1 = does not open eyes 2 = opens eyes in response to noxious stimuli 3 = opens eyes in response to voice 4 = opens eyes spontaneously	*Eye Response* 4 = eyelids open or opened, tracking, or blinking to command 3 = eyelids open but not tracking 2 = eyelids closed but open to loud voice 1 = eyelids closed but open to pain 0 = eyelids remain closed with pain
Verbal Output 1 = makes no sounds 2 = makes incomprehensible sounds 3 = utters inappropriate words 4 = confused and disoriented 5 = speaks normally and oriented	*Motor Response* 4 = thumbs-up, fist, or peace sign 3 = localizing to pain 2 = flexion response to pain 1 = extension response to pain 0 = no response to pain or generalized myoclonus status
Motor Response (Best) 1 = makes no movements 2 = extension to painful stimuli 3 = abnormal flexion to painful stimuli 4 = flexion/withdrawal to painful stimuli 5 = localized to painful stimuli 6 = obeys commands	*Brainstem Reflexes* 4 = pupil and corneal reflexes present 3 = one pupil wide and fixed 2 = pupil or corneal reflexes absent 1 = pupil and corneal reflexes absent 0 = absent pupil, corneal, and cough reflex
	Respiration 4 = not intubated, regular breathing pattern 3 = not intubated, Cheyne-Stokes breathing pattern 2 = not intubated, irregular breathing 1 = breathes above ventilatory rate 0 = breathes at ventilator rate or apnea

From Edlow JA, Rabinstein A, Traub SJ, Wijdicks EFM: Diagnosis of reversible causes of coma. Lancet 384:2064-2076, 2014.

Clinical Manifestations

The hallmark of **severe TBI** is coma (**GCS score 3-8**). Often, coma is seen immediately after the injury and is sustained. In some cases, such as with an epidural hematoma, a child may be alert on presentation but may deteriorate after a period of hours. A similar picture can be seen in children with diffuse swelling, in whom a *talk-and-die* scenario has been described. Clinicians should also not be lulled into underappreciating the potential for deterioration of a child with **moderate TBI** (**GCS score 9-12**) with a significant contusion, because progressive swelling can potentially lead to devastating complications. In the comatose child with severe TBI, the second key clinical manifestation is the development of intracranial hypertension. The development of increased ICP with impending herniation may be heralded by new-onset or worsening headache, depressed level of consciousness, vital sign changes (hypertension, bradycardia, irregular respirations), and signs of 6th (lateral rectus palsy) or 3rd (anisocoria [dilated pupil], ptosis, down-and-out position of globe as a result of rectus muscle palsies) cranial nerve compression. Increased ICP is managed with continuous ICP monitoring, as well as monitoring for clinical signs of increased ICP or impending herniation. The development of brain swelling is progressive. Significantly raised ICP (>20 mm Hg) can occur early after severe TBI, but peak ICP generally is seen at 48-72 hr.

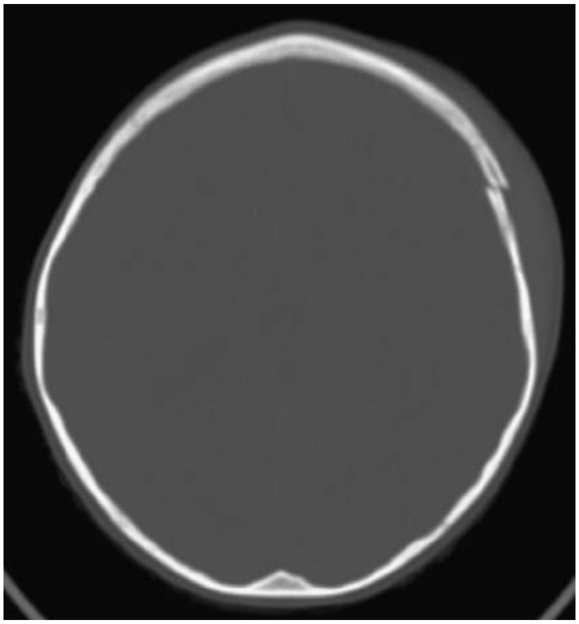

Figure 68-4 Mildly displaced skull fracture seen on CT imaging (bone window view) in a 4 yr old who fell and hit her head on a curb.

Figure 68-5 Left frontal epidural hematoma observed on CT imaging in a 12 yr old child who fell off his bike onto concrete surface.

Need for ICP-directed therapy may persist for longer than a week. A few children have coma without increased ICP, resulting from axonal injury or brainstem injury. *In addition to head trauma, it is critical to identify potential cervical spine injury.*

Laboratory Findings

Cranial CT should be obtained immediately after resuscitation and cardiopulmonary stabilization (Figs. 68-4 to 68-10). In some cases, magnetic resonance imaging can be diagnostic (Fig. 68-11). Generally, other laboratory findings are normal in isolated TBI, although occasionally coagulopathy or the development of the syndrome of inappropriate antidiuretic hormone secretion or, rarely, cerebral salt wasting is seen. In the setting of TBI with polytrauma, other injuries can result in laboratory abnormalities, and a full trauma survey is important in all patients with severe TBI (see Chapter 72).

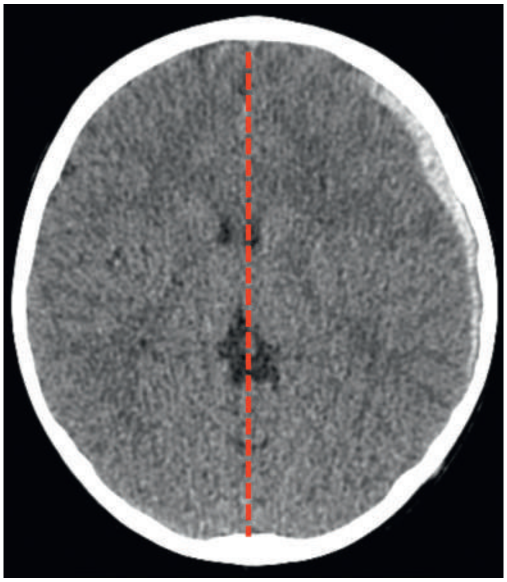

Figure 68-6 Left subdural hematoma observed on CT imaging in a 10 yr old child after a motor vehicle accident. Note, there is effacement of the left lateral ventricle and midline shift noted (see *dotted line* for midline reference).

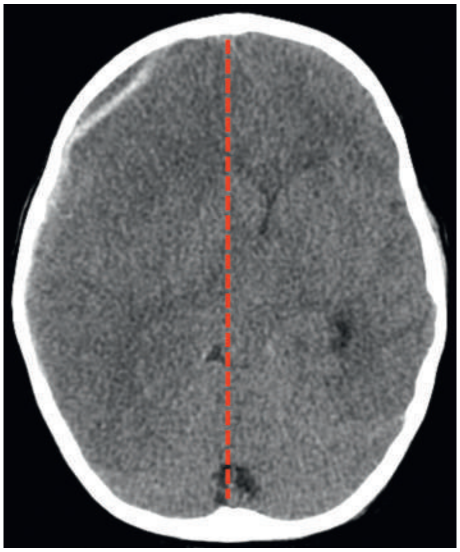

Figure 68-7 Hyperacute right frontal subdural hematoma observed on CT imaging in a 5 yr old after a motor vehicle accident. Note that the hyperacute aspect of the subdural hematoma is dark on CT imaging in the early stage after injury. Also, note that there is marked midline shift of intracranial contents, as both lateral ventricles are displaced into the left side of the skull.

Diagnosis and Differential Diagnosis

In severe TBI, the diagnosis is generally obvious from the history and clinical presentation. Occasionally, TBI severity can be overestimated because of concurrent alcohol or drug intoxication. The diagnosis of TBI can be problematic in cases of abusive head trauma or following an anoxic event such as drowning or smoke inhalation.

Treatment

Infants and children with severe or moderate TBI (GCS score 3-8 or 9-12, respectively) receive intensive care unit (ICU) monitoring. Evidence-based guidelines for management of severe TBI have been published (Fig. 68-12). This approach to ICP-directed therapy is also reasonable for other conditions in which ICP is monitored. Care involves a multidisciplinary team comprising pediatric caregivers from

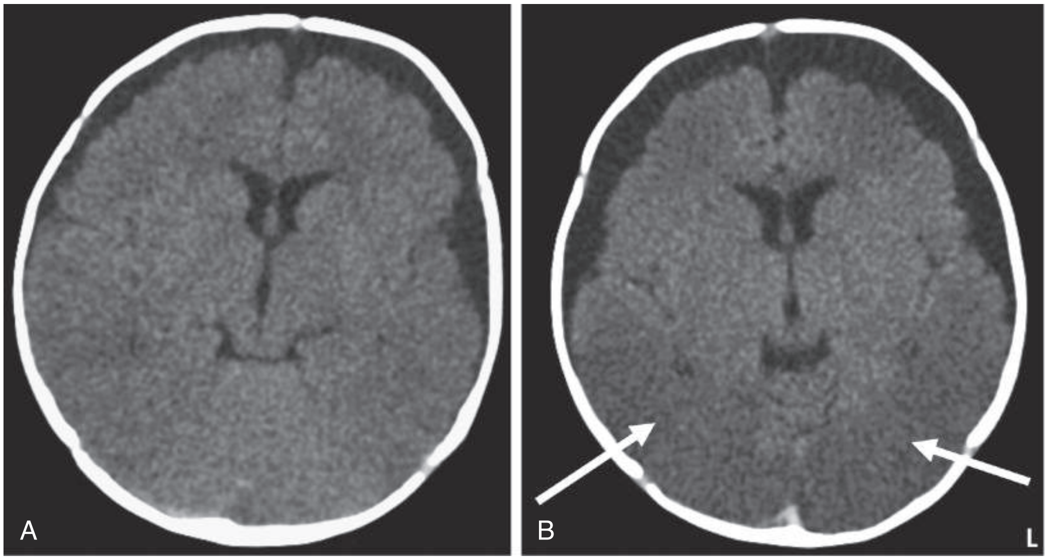

Figure 68-8 In a 3 mo old child who suffered from abusive head trauma, initial CT imaging *(A)* demonstrates chronic subdural hematoma bilaterally. Three days after hospitalization *(B)*, the subdural hematomas are slightly larger but infarctions are noted in the posterior areas of brain parenchyma (see *arrows*).

Figure 68-9 In a 16 yr old who fell off of his dirt bike, CT imaging demonstrates intraparenchymal hemorrhage and significant surrounding edema (*arrow*).

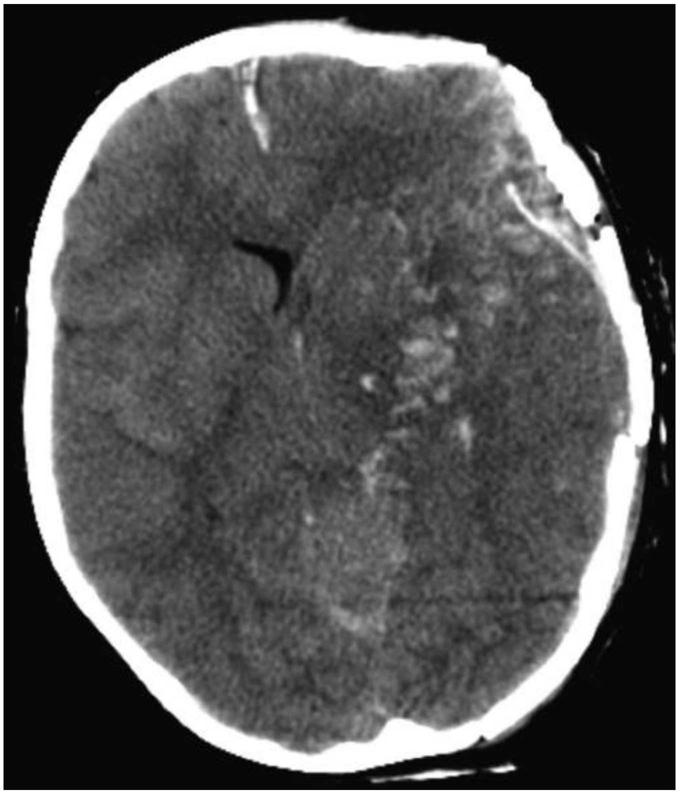

Figure 68-10 An 11 yr old child was hit in the head by a horse, and CT imaging demonstrates multiple, comminuted skull fractures with fragments of bone within the brain parenchyma, multifocal areas of intraparenchymal hemorrhage, and obliteration of the left lateral ventricle.

neurologic surgery, critical care medicine, surgery, and rehabilitation, and is directed at preventing secondary insults and managing raised ICP. Initial stabilization of infants and children with severe TBI includes rapid sequence tracheal intubation with spine precautions along with maintenance of normal extracerebral hemodynamics, including blood gas values (partial pressure arterial oxygen, $Paco_2$), mean arterial pressure, and temperature. Intravenous fluid boluses may be required to treat hypotension. Euvolemia is the target, and hypotonic fluids should be rigorously avoided; normal saline is the fluid of choice. Pressors may be needed as guided by monitoring of central venous pressure, with avoidance of both fluid overload and exacerbation of brain edema. A trauma survey should be performed. Once stabilized, the patient should be taken for CT scanning to rule out the need for emergency neurosurgical intervention. If surgery is not

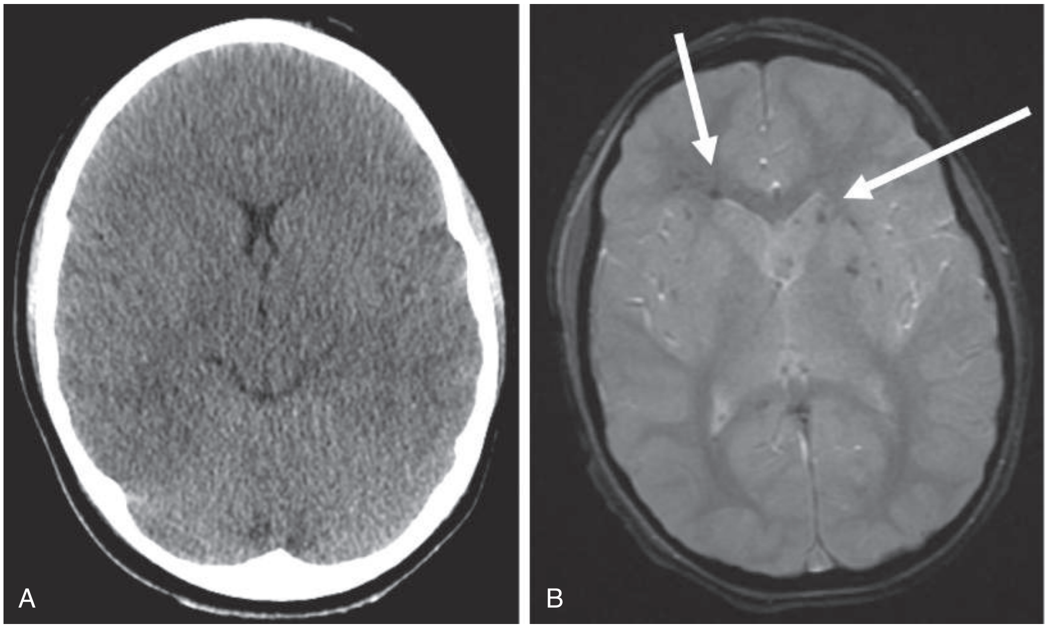

Figure 68-11 In a 6 yr old child who was hit by a car while riding his bike, initial CT imaging demonstrates no obvious abnormality (*A*). However, immediate MRI demonstrates multiple areas of punctate hemorrhages (lucencies) consistent with diffuse axonal injury (*B, arrows*).

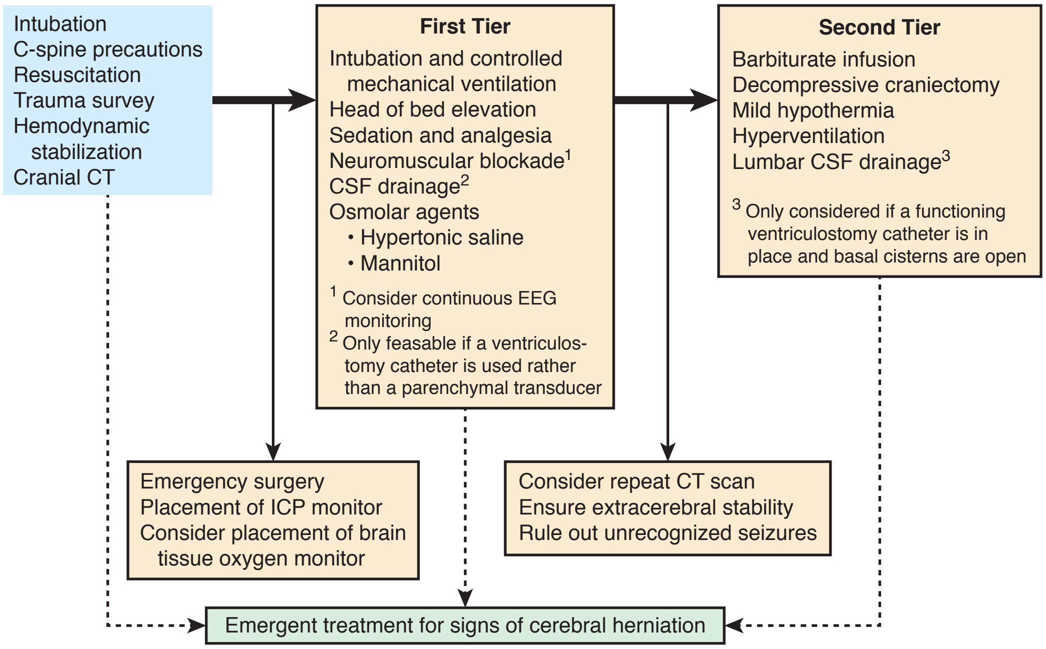

Figure 68-12 Schematic outlining the approach to management of a child with severe TBI. It is based on the 2012 guidelines for the management of severe TBI, along with minor modifications from later literature. The ICP and CPP targets are discussed in the text. This schematic is specifically presented for severe TBI, for which the experience with ICP-directed therapy is greatest. Nevertheless, the general approach provided here is relevant to the management of intracranial hypertension in other conditions for which evidence-based data on ICP monitoring and ICP-directed therapy are lacking. Please see text for details.

required, an ICP monitor should be inserted to guide the treatment of intracranial hypertension. Serial assessment of brain edema on CT scan can also help guide management.

During stabilization or at any time during the treatment course, patients can present with signs and symptoms of cerebral **herniation** (pupillary dilation, systemic hypertension, bradycardia, extensor posturing). Because herniation and its devastating consequences can sometimes be reversed if promptly addressed, it should be treated as a medical emergency, with use of hyperventilation with a fraction of inspired oxygen of 1.0, and intubating doses of either thiopental or pentobarbital and either mannitol (0.25-1.0 g/kg IV) or hypertonic saline (3% solution, 5-10 mL/kg IV).

ICP should be maintained <20 mm Hg; age-dependent CPP targets are ≈50 mm Hg for children 2-6 yr of age; 55 mm Hg for those 7-10 yr of age; and 65 mm Hg for those 11-16 yr of age. First-tier therapy includes elevation of the head of the bed, ensuring midline positioning of the head, controlled mechanical ventilation, and sedation and analgesia (i.e., benzodiazepines and narcotics). If neuromuscular blockade is needed, it may be desirable to monitor EEG continuously because *status epilepticus* can occur; this complication will not be recognized

in a paralyzed patient and is associated with raised ICP and unfavorable outcome. If a ventricular rather than parenchymal catheter is used to monitor ICP, therapeutic CSF drainage is available and can be provided either continuously (often targeting an ICP >5 mm Hg) or intermittently in response to ICP spikes, generally 20 mm Hg. Other first-tier therapies include the osmolar agents mannitol (0.25-1.0 g/kg IV over 20 min), given in response to ICP spikes >20 mm Hg or with a fixed (q4-6h) dosing interval, and hypertonic saline (often given as a continuous infusion of 3% saline at 0.1-1.0 mL/kg/hr). Choice of osmolar agent depends on the preference of the treating center. These 2 agents can be used concurrently. It is recommended to avoid serum osmolality >320 mOsm/L. A Foley urinary catheter should be placed to monitor urine output.

If ICP remains refractory to treatment, careful reassessment of the patient is needed to rule out unrecognized hypercarbia, hypoxemia, fever, hypotension, hypoglycemia, pain, and seizures. Repeat imaging should be considered to rule out a surgical lesion. Guidelines-based second-tier therapies for refractory raised ICP are available, but evidence favoring a given second-tier therapy is limited. In some centers, decompressive craniectomy is used. Others use a pentobarbital infusion, with a loading dose of 5-10 mg/kg over 30 min followed by 5 mg/kg every hour for 3 doses and then maintenance with an infusion of 1 mg/kg/hr. Careful blood pressure monitoring is required because of the possibility of drug-induced hypotension and the frequent need for support with fluids and/or pressors. Mild hypothermia (32-34°C [89.6-93.2°F]) to control refractory ICP can be induced and maintained by means of surface cooling. Sedation and neuromuscular blockade are used to prevent shivering, and rewarming should be slow, no faster than 1°C (1.8°F) every 4-6 hr. Hypotension should be prevented during rewarming. Refractory raised ICP can also be treated with hyperventilation ($Paco_2$ = 25-30 mm Hg). Other second-tier therapies (e.g., lumbar CSF drainage) are options.

Supportive Care

Euvolemia should be maintained, and isotonic fluids are recommended until resolution of intracranial hypertension. The syndrome of inappropriate antidiuretic hormone secretion and salt wasting can develop and are important to differentiate, because management of the former is fluid restriction and that of the latter is sodium replacement. Severe hyperglycemia (blood glucose level >200 mg/dL) should be avoided and treated. The blood glucose level should be monitored frequently. Early nutrition with enteral feedings is advocated. Corticosteroids should generally not be used unless adrenal insufficiency is documented. Tracheal suctioning can exacerbate raised ICP. Timing of the use of sedation around suctioning events and/or use of tracheal or IV lidocaine can be helpful. Seizures are common after severe acute TBI. Early posttraumatic seizures (within 1 wk) will complicate management of TBI and are often difficult to treat. Anticonvulsant prophylaxis with fosphenytoin, carbamazepine, or levetiracetam is a common treatment option. Late posttraumatic seizures (≥7 days after TBI) and, if recurrent, late posttraumatic epilepsy are not prevented by prophylactic anticonvulsants, whereas early posttraumatic seizures are prevented by initiating anticonvulsants soon after TBI. Antifibrinolytic agents (tranexamic acid) reduce hemorrhage size as well as the development of new focal ischemic cerebral lesions, and improve survival in adults with severe traumatic brain injury.

Prognosis

Mortality rates for children with severe TBI who reach the pediatric ICU range between 10% and 30%. Ability to control ICP is related to patient survival, and the extent of cranial and systemic injuries correlates with quality of life. Motor and cognitive sequelae resulting from severe TBI generally benefit from rehabilitation to minimize long-term disabilities. Recovery from TBI may take months to achieve. Physical therapy, and in some centers methylphenidate, helps with motor and behavioral recovery. Pituitary insufficiency may be an uncommon but significant complication of severe TBI.

Bibliography is available at Expert Consult.

68.1 Brain Death

K. Jane Lee

Brain death is the irreversible cessation of all functions of the entire brain, including the brainstem. It is also known as the determination of death using neurologic criteria. Although brain death is legally accepted in the United States as the equivalent of death from the irreversible cessation of circulatory and respiratory functions, it can be difficult to understand and is not universally accepted.

EPIDEMIOLOGY

In children, brain death most commonly develops following TBI (including brain injury from nonaccidental trauma) or asphyxial injury. Pathogenesis is multifactorial, with the end result being irreversible loss of brain and brainstem function.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Guidelines for the determination of brain death in children were first published in 1987 by a Special Task Force to the American Academy of Pediatrics. These were revised for the first time in 2011 by a combined group from the Society of Critical Care Medicine, the American Academy of Pediatrics, and the Child Neurology Society.

Brain death is primarily a clinical diagnosis. Although ancillary tests such as EEG and CBF studies are sometimes used to assist in making the diagnosis, repeated clinical examination is the standard for diagnosis. The 3 key components of clinical brain death diagnosis are demonstrations of coexisting **irreversible coma with a known cause**, **absence of brainstem reflexes**, and **apnea**.

Before a determination of brain death may be made, it is of utmost importance that the cause of the coma be determined through the use of historical, radiologic, and laboratory data to rule out a reversible condition. Potentially reversible causes of coma include metabolic disorders; toxins; sedative drugs; paralytic agents; hypothermia; hypoxia; hypotension/shock; recent cardiopulmonary resuscitation; hypoglycemia/hyperglycemia; hyponatremia/hypernatremia; hypercalcemia; hypermagnesemia; nonconvulsive status epilepticus; hypothyroidism; hypocortisolism; hypercarbia; liver or renal failure; sepsis; meningitis; encephalitis; subarachnoid hemorrhage; and surgically remediable brainstem lesions. Confounding factors must be corrected prior to initiation of brain death assessment.

Coma

The state of **coma** requires that the patient be unresponsive, even to noxious stimuli. Any purposeful motor response, such as localization, does not constitute coma. Likewise, any posturing (decerebrate or decorticate) is not consistent with coma, and therefore not consistent with brain death. The presence of spinal cord reflexes—even complex reflexes—does not preclude the diagnosis of brain death.

Brainstem Reflexes

Brainstem reflexes must be absent. Table 68-2 lists the brainstem reflexes to be tested, the brainstem location of each reflex, and the result of each test that is consistent with a diagnosis of brain death.

Apnea

Apnea is the absence of respiratory effort in response to an adequate stimulus. A partial pressure of carbon dioxide (pCO_2) value ≥60 mm Hg *and* >20 mm Hg above baseline is considered sufficient. Apnea is clinically confirmed through the apnea test. Because the apnea test has the potential to destabilize the patient, this test is performed only if the first 2 criteria for brain death (irreversible coma and absence of brainstem reflexes) are already confirmed.

The **apnea test** assesses the function of the medulla in driving ventilation. It is performed by first ensuring appropriate hemodynamics and temperature and the absence of apnea-producing drug effects or significant metabolic derangements. The patient is then preoxygenated with 100% oxygen for approximately 10 minutes and ventilation is adjusted to achieve a pCO_2 of approximately 40 mm Hg. A baseline

Table 68-2 Brainstem Reflex Testing to Determine Brain Death

BRAINSTEM REFLEX	AREA TESTED	HOW TO PERFORM THE EXAM	EXPLANATION OF RESULTS
Pupillary light reflex	CN II and III, midbrain	Shine a light into the eyes while closely observing pupillary size	Midposition (4-6 mm) or fully dilated pupils that are not reactive to light are consistent with brain death. Pinpoint pupils, even if nonreactive, suggest intact function of the Edinger-Westphal nucleus in the midbrain and are therefore not consistent with brain death.
Oculocephalic reflex (doll's-eyes reflex)	CN III, VI, and VIII, midbrain, pons	Manually rotate the patient's head side to side and closely watch the position of the eyes. Should not be performed in a patient with a cervical spine injury.	In an intact patient, the eyes remain fixed on a distant spot, as if maintaining eye contact with that spot. In an exam consistent with brain death, the eyes move in concert with the patient's head movement.
Corneal reflex	CN III, V, and VII, pons	Touch the patient's cornea with a cotton swab.	In the intact patient, the touch results in eyelid closure, and the eye may rotate upward. In an exam consistent with brain death, there is no response.
Oculovestibular reflex	CN III, IV, VI, and VIII, pons, midbrain	Irrigate the tympanic membrane with iced water or saline and look for eye movement.	Absence of eye movement is consistent with brain death.
Gag and cough reflex	CN IX and X, medulla	Touch the posterior pharynx with a tongue depressor or a cotton-tipped swab to stimulate a gag. Advance a suction catheter through the endotracheal tube to the carina to stimulate a cough.	Absence of both a cough and a gag is consistent with brain death.

CN, cranial nerve.

blood gas result documents the starting values. During the test, oxygenation can be maintained with 100% oxygen via a T-piece attached to the endotracheal tube or via a resuscitation bag such as a Mapleson device. Throughout the test, the child's hemodynamics and oxygen saturation are monitored while the physician observes for respiratory efforts. A blood gas sample is obtained approximately 10 min into the test and every 5 min thereafter until the target pCO_2 is surpassed; ventilatory support is resumed at that time. If at any point during the test the patient becomes hypoxic or hypotensive, the test is aborted and ventilatory support is resumed. Absence of respiratory efforts with a pCO_2 ≥60 mm Hg and >20 mm Hg above baseline is consistent with brain death.

OBSERVATION PERIODS

To establish the diagnosis of brain death, the findings must remain consistent for 2 examinations separated by an observation period. Recommended observation periods are 24 hr for neonates from 37 wk gestation to term infants 30 days old, and 12 hr for infants and children older than 30 days. An observation period of 24-48 hr prior to initiation of brain death assessment is recommended following CPR or severe acute brain injury.

ANCILLARY STUDIES

Ancillary studies are not required for the diagnosis of brain death unless the clinical examination including the apnea test cannot be safely or reliably completed. Examples include cervical spinal cord injury, presence of high-therapeutic or supratherapeutic levels of sedative medications, or hemodynamic instability or desaturation during an apnea test. Ancillary studies may also be used to shorten the recommended observation period. In this case, 2 complete clinical examinations, including apnea test, should be completed and documented along with the ancillary study.

The 2 most commonly used ancillary tests are EEG and radionuclide CBF studies. A valid **EEG** to support suspected brain death must be performed according to accepted technical requirements, under conditions of normothermia and appropriate hemodynamics, and in the absence of drug levels sufficient to suppress the EEG response. An EEG that demonstrates **electrocerebral silence** over a 30 min recording time under these conditions supports the diagnosis of brain death. Advantages of this study are its wide availability and low risk. Disadvantages include potential confounders, such as artifact in the tracing and the presence of suppressing levels of drugs such as barbiturates.

A **radionuclide CBF study** consists of intravenous injection of a radiopharmaceutical agent followed by imaging of the brain to look for cerebral uptake. Like EEG, nuclear medicine scans are widely available and low risk. Unlike EEG, these studies are not affected by drug levels. A study that shows absence of uptake in the brain demonstrates absence of CBF and is supportive of brain death. Four-vessel intracranial contrast angiography was previously used as the definitive ancillary test, but practical technical difficulties and risks have led to the use of nuclear medicine scans instead.

Interpretation of both EEG and radionuclide CBF studies should be done by appropriately trained and qualified individuals. If the studies show electrical activity or presence of CBF, brain death cannot be declared. A 24 hr waiting period is recommended prior to repeating the clinical examination or ancillary study.

DOCUMENTATION

Documentation is an important aspect of diagnosing brain death. Complete documentation should include statements of the following:

1. Etiology and irreversibility of the coma.
2. Absence of confounding factors: hypothermia, hypotension, hypoxia, significant metabolic derangement, significant drug levels.
3. Absence of motor response to noxious stimulation.
4. Absence of brainstem reflexes: pupillary light reflex, oculocephalic/oculovestibular reflex, corneal reflex, cough and gag reflex.
5. Absence of respiratory effort in response to an adequate stimulus; blood gas values should be documented at the beginning and end of the apnea test.

SUPPORTIVE CARE

Following a diagnosis of brain death, supportive care may continue for hours to days as the family makes decisions about potential organ donation and comes to terms with the diagnosis. A diagnosis of brain death may not be accepted by the family for personal, religious, or

cultural reasons. It is important for care providers to be patient and supportive of the family dealing with this difficult situation.

OBJECTIONS TO THE IDEA OF BRAIN DEATH

Although the concept of brain death is widely accepted and very useful in facilitating organ transplantation, it is not accepted by all. Several countries do not recognize brain death, and some individuals, both medical personnel and laypeople, object to the idea of brain death.

It has been pointed out that some patients who meet brain death criteria continue to show evidence of integrative functioning, such as control over free-water homeostasis (absence of diabetes insipidus), control of temperature regulation, capacity for growth and wound healing, and variability of heart rate and blood pressure in response to stimulus. Along with scientific arguments, there are also philosophical arguments about what constitutes death and whether a person who lacks function of the brain, but not of the body, is truly dead.

Chapter 69

Syncope

George F. Van Hare

Syncope is defined as a sudden transient loss of consciousness with inability to maintain postural tone. The most common cause of syncope in the normal pediatric population is **neurocardiogenic syncope**, also known as vasovagal syncope (Table 69-1). Although this type of syncope is very common in adolescence and has an excellent prognosis, other causes for loss of consciousness are more dangerous, thus syncope may be the first sign of more serious conditions (Table 69-2). Indeed, the occurrence of syncope may well be the pediatrician's best opportunity to diagnose a life-threatening condition before the patient subsequently succumbs. The task of the clinician, therefore, is not only to counsel the family and the patient concerning the common form, but also to rule out a number of important life-threatening cardiac problems.

EPIDEMIOLOGY

Most syncope presents during adolescence, typically between 11 and 13 yr of age. The incidence is somewhat higher in girls than in boys. Approximately 25% of all young adults will have experienced at least 1 episode of neurocardiogenic syncope.

MECHANISMS

Syncope by whatever mechanism is caused by a lack of adequate cerebral blood flow with loss of consciousness and inability to see remain upright. The mechanisms underlying neurocardiogenic syncope are not completely understood but seem to involve some trigger event that leads to vasodilation, venous pooling in the lower part of the body exacerbated by prolonged standing, decreased cardiac filling with compensatory sinus tachycardia and sympathetic nervous system activity, and, finally, activation of cardiac C fibers leading to reflex bradycardia. The typical event is triggered by a variety of factors, such as disgust, the site of blood, other emotional reactions, particular smells, or simply prolonged standing (see Table 69-1). Most patients display a mixed picture with both blood pressure and heart rate changes. Prior to syncope, the blood pressure declines and the heart rate increases, and with loss of consciousness there is often significant bradycardia. Other patients display a principally vasopressor response with a drop in blood pressure as the most important feature. Still others primarily have a cardioinhibitory response in which sudden profound bradycardia or asystole occurs with little or no change in blood pressure prior to the event. Making the distinction between these various patterns leading

Eisenmenger syndrome
Dissecting aortic aneurysm (Marfan syndrome)
Cardiac tumor

to syncope is important for treatment considerations. In any case, with loss of consciousness and the assumption of supine posture, venous return and atrial filling dramatically increases and adequate blood pressure returns quickly.

Primary cardiac causes of syncope (see Table 69-2) include arrhythmias (see Chapter 435) such as **long QT syndrome**, **Wolff-Parkinson-White syndrome** (particularly with atrial fibrillation), ventricular tachycardia, and occasionally supraventricular tachycardia. Ventricular tachycardia may be associated with **hypertrophic cardiomyopathy**, repaired **congenital heart disease**, or a genetic cause such as **catecholaminergic polymorphous ventricular tachycardia**. Other arrhythmias that may lead to syncope are bradyarrhythmias such as **sinus node dysfunction** and high-grade 2nd or 3rd degree atrioventricular (AV) block. Patients with **congenital complete AV** block may present with syncope. Syncope may also be caused by cardiac obstructive lesions, such as **critical aortic stenosis,** or coronary artery anomalies, such as an **aberrant left coronary artery arising from the right sinus of Valsalva**. Finally, patients with **primary pulmonary hypertension** or **Eisenmenger syndrome** may experience syncope. In all of the obstructive forms of syncope, exercise increases the likelihood of an episode as the obstruction interferes with the ability of the heart to increased cardiac output in response to exercise.

Noncardiac causes of loss of consciousness include epilepsy, but may also include basilar artery migraine, hysterical syncope, and pseudo-seizures (see Table 69-1). Occasionally patients with narcolepsy may present as syncope. Hypoglycemia and hyperventilation may also present with syncope.

EVALUATION

The most important goal in the evaluation of the new patient with syncope is to diagnose life-threatening causes of syncope so that these causes can be managed. Many patients presenting with sudden cardiac arrest caused by conditions such as long QT syndrome will have previously experienced an episode of syncope, and so the presentation with syncope is an opportunity to prevent sudden death.

The most important tool in evaluation is a careful history. The patient with neurocardiogenic syncope will be able to describe the circumstances of the event and specific prodromal symptoms. Typically, the patient will have been standing for a period of time, often on a hot day, or has gotten up suddenly from sleep or resting in a supine position. Occurrence in the shower is common, presumably caused by standing and vasodilation caused by hot water. For boys, the occurrence while urinating while standing is sometimes reported. The occurrence of syncope in girls while sitting or standing and having their hair brushed is common. Typical prodromal symptoms prior to syncope include lightheadedness, dizziness, nausea, sweating, and feeling hot or cold. Patients may report visual field changes and "rushing" in their ears. Witnesses will usually note extreme pallor or a gray color change. Injury to the patient as a result of the episode of syncope is unusual in common syncope, as the patient usually has adequate prodromal symptoms to avoid injury. Loss of consciousness is generally transient once the patient becomes supine; the loss of consciousness resolves rapidly (seconds to minutes), and there is no clear postevent state of sleepiness. Often, patients will describe other episodes with similar prodromal symptoms which did not lead to complete loss of consciousness but were aborted, often because the patient was able to assume recumbent posture. Some patients have a few tonic–clonic movements while unconscious, which resolve within seconds, and do not signify a seizure disorder.

The characteristics of cardiac syncope not due to neurocardiogenic mechanisms are generally quite different. A number of "red flags" can be identified that should lead the clinician to be suspicious that the mechanism is a life-threatening cardiac cause rather than simple fainting (Table 69-3). The occurrence during exercise suggests an arrhythmia or coronary obstruction. Injury as a result of an episode of syncope suggests sudden occurrence with a lack of adequate prodromal symptoms, and suggests an arrhythmia. The occurrence of syncope while recumbent would be quite unusual in a patient with neurocardiogenic syncope and therefore raises the possibility of a cardiac or neurologic cause. Occasionally, a patient with syncope caused by a tachyarrhythmia will report the sensation of a racing heart prior to the event, but this is actually unusual.

Table 69-3	"Red Flags" in the Evaluation of Patients with Syncope
Syncope with activity or exercise or supine	
Syncope not associated with prolonged standing	
Syncope precipitated by loud noise or extreme emotion	
Absence of presyncope or lightheadedness	
Family history of syncope, drowning, sudden death, familial ventricular arrhythmia syndromes*, cardiomyopathy	
Syncope requiring CPR

Increased apical impulse (tachycardia)	
Irregular rhythm	
Hypo- or hypertension	
Clubbing	
Cyanosis	

*Long Qt syndrome, Brugada syndrome, catecholamine polymorphic ventricular tachycardia, arrhythmogenic right ventricular dysplasia.

A careful family history is essential in evaluation of syncope. Specifically, if there are first-degree relatives with inherited syndromes, such as a long QT syndrome or hypertrophic cardiomyopathy, this should lead to more specific evaluation of the patient. Also, if there are relatives who have died suddenly in young age without a clear and convincing cause, inherited cardiac arrhythmias or cardiomyopathies should also be suspected.

Patients with a history of heart disease, especially cardiac repair, may have causes that are specific to their repair. Sinus node dysfunction is common after the Senning or Mustard procedure for transposition of the great vessels. Ventricular tachycardia may be seen following repair of tetralogy of Fallot. A patient with a history of septal defect repair should be evaluated for the late occurrence of AV block, and patients with an implanted pacemaker should be evaluated for pacemaker lead failure.

The physical examination may also offer clues (see Table 69-3). Patients with hypertrophic cardiomyopathy may have a prominent cardiac impulse and/or an ejection murmur, as will patients with aortic stenosis. The patient with primary pulmonary hypertension will have a loud and single second heart sound and may also have an ejection click and the murmur of pulmonary insufficiency. Scars from prior cardiac surgery and pacemaker implantation would be evident.

All patients presenting with a first episode of syncope should have an electrocardiogram obtained, looking primarily for QT interval prolongation, preexcitation, ventricular hypertrophy, T-wave abnormalities, and conduction abnormalities. Other tests that may be needed depending on the results of the initial evaluation may include echocardiography, cardiac MRI, or 24-hr Holter monitoring. In patients for whom there is a strong suspicion of a paroxysmal arrhythmia, an implantable loop recorder may be the most effective means of diagnosis.

Tilt-table testing was originally developed by the military and was applied to the general population of otherwise normal individuals who have experienced syncope. While patients with neurocardiogenic syncope often will experience an episode during the tilt-table test, the test is poorly reproducible and neither particularly sensitive nor

specific. The use of tilt-table testing for the otherwise normal adolescent with simple fainting is discouraged. Some pediatric cardiologists still employ the test in severely affected individuals who are not responding to standard therapy, as a way of planning more aggressive therapy.

Additional tests to look for anemia, hypoglycemia, drugs of abuse, and other etiologies noted in Table 69-1 will be determined by the history and physical exam.

TREATMENT

Most patients with neurocardiogenic syncope will experience eventual resolution by adulthood; many even get better spontaneously within a few months or years. Many therapies have been employed for this condition, but it is difficult to determine which ones are truly effective because of the lack of randomized prospective studies. Nonetheless, initial salt and water supplementation is commonly recommended, particularly in those who have a low-salt diet or who have limited their fluid intake. A reasonable second step is treatment with fludrocortisone, a mineralocorticoid that promotes sodium and water retention with potassium loss. In patients who have a prominent low-blood-pressure response, the α-agonist midodrine may be useful. Both midodrine and fludrocortisone should be managed with careful monitoring of the supine blood pressure, as they may lead to supine hypertension. Some have advocated the use of β blockers such as, pindolol, which offers some advantages because of its intrinsic sympathomimetic activity; randomized prospective trials have not supported the effectiveness of beta blockers. Occasionally, the use of selective serotonin reuptake inhibitors is effective in certain patients. Occasional patients who present with profound bradycardia or asystole can be helped by implantation of a dual-chamber transvenous pacemaker with programmed hysteresis (rapid pacing in response to a sudden drop in heart rate).

The most important therapeutic step is educational. Once the young patient is aware of the importance of the prodromal symptoms, they can take appropriate steps to change position and not attempt to remain standing. In many, this is all that is necessary to adequately manage their symptoms.

Bibliography is available at Expert Consult.

69.1 Disorders of Orthostatic Intolerance

George F. Van Hare

Postural orthostatic tachycardia syndrome (POTS) is a female-predominant condition in which the patient experiences an impressive and symptomatic elevation in heart rate on standing. This orthostatic intolerance disorder manifests with presyncopal symptoms, lightheadedness, dizziness, palpitations, leg weakness and tremulousness on standing. An orthostatic heart rate of >120 beats/min and a rise in heart rate of ≥30 beats/min with 5 min of standing suggest the diagnosis. *This should not be confused with neurocardiogenic syncope*. Patients with POTS often also complain of other symptoms, such as fatigue, chest pain, headaches, abdominal pain, bloating, nausea, emesis, sleep disturbances, and fatigue. There is an overlap with patients with POTS and chronic fatigue syndrome or functional gastrointestinal disorders. Many patients are evaluated in dysautonomia programs and may have evidence of a **small fiber polyneuropathy**. Treatment of POTS is symptomatic and often not particularly successful. The use of β blockers may be effective; some physicians have advised increase physical activity through cardiac rehabilitation.

Juvenile-onset widespread pain syndromes associated with a small fiber polyneuropathy (dysautonomia) have associated gastrointestinal, cardiovascular, fatigue, headache symptoms as well as erythromelalgia. Steroids or intravenous immunoglobulin has been used to treat this disorder.

Chapter 70

Shock

David A. Turner and Ira M. Cheifetz

Shock is an acute process characterized by the body's inability to deliver adequate oxygen to meet the metabolic demands of vital organs and tissues. Insufficient oxygen at the tissue level is unable to support normal aerobic cellular metabolism, resulting in a shift to less-efficient anaerobic metabolism. As shock progresses, increases in tissue oxygen extraction are unable to compensate for this deficiency in oxygen delivery, leading to progressive clinical deterioration and lactic acidosis. If inadequate tissue perfusion persists, adverse vascular, inflammatory, metabolic, cellular, endocrine, and systemic responses worsen physiologic instability.

Compensation for inadequate oxygen delivery involves a complex set of responses that attempt to preserve oxygenation of the vital organs (i.e., brain, heart, kidneys, liver) at the expense of other organs (i.e., skin, gastrointestinal tract, muscles). Of importance, the brain is especially sensitive to periods of poor oxygen supply, given its lack of capacity for anaerobic metabolism. Initially, shock is often well compensated, but it may rapidly progress to an uncompensated state requiring more aggressive therapies to achieve clinical recovery or improvement. The combination of a continued presence of an inciting trigger and the body's exaggerated and potentially harmful neurohumoral, inflammatory, and cellular responses leads to the progression of shock. Irrespective of the underlying cause of shock, the specific pattern of response, pathophysiology, clinical manifestations, and treatments may vary significantly, depending on the specific etiology (which may be unknown), the clinical circumstances, and an individual patient's biologic response to the shock state. Untreated shock causes irreversible tissue and organ injury (i.e., irreversible shock) and, ultimately, death.

EPIDEMIOLOGY

Shock occurs in approximately 2% of all hospitalized infants, children, and adults in developed countries, and the mortality rate varies substantially depending on the etiology and clinical circumstances. Most patients who do not survive, do not die in the acute hypotensive phase of shock, but rather as a result of associated complications and **multiple organ dysfunction syndrome (MODS).** MODS is defined as any alteration of organ function that requires medical support for maintenance, and the presence of MODS in patients with shock substantially increases the probability of death. In pediatrics, educational efforts and the utilization of standardized management guidelines that emphasize early recognition and intervention along with the rapid transfer of critically ill patients to a pediatric intensive care unit have led to decreases in the mortality rate for shock (Fig. 70-1).

DEFINITION

Shock classification systems generally define 5 major types of shock: hypovolemic, cardiogenic, distributive, obstructive, and septic (Table 70-1). **Hypovolemic shock,** the most common cause of shock in children worldwide, is most frequently caused by diarrhea, vomiting, or hemorrhage. **Cardiogenic shock** is seen in patients with either congenital heart disease (before or after surgery, including heart transplantation) or with congenital or acquired cardiomyopathies, including acute myocarditis. **Obstructive shock** stems from any lesion that creates a mechanical barrier that impedes adequate cardiac output, which include pericardial tamponade, tension pneumothorax, pulmonary embolism, and ductus-dependent congenital heart lesions. **Distributive shock** is caused by inadequate vasomotor tone, which leads to capillary leak and maldistribution of fluid into the interstitium. **Septic shock** is often discussed synonymously with distributive shock, but the septic process usually involves a more complex interaction of distributive, hypovolemic, and cardiogenic shock.

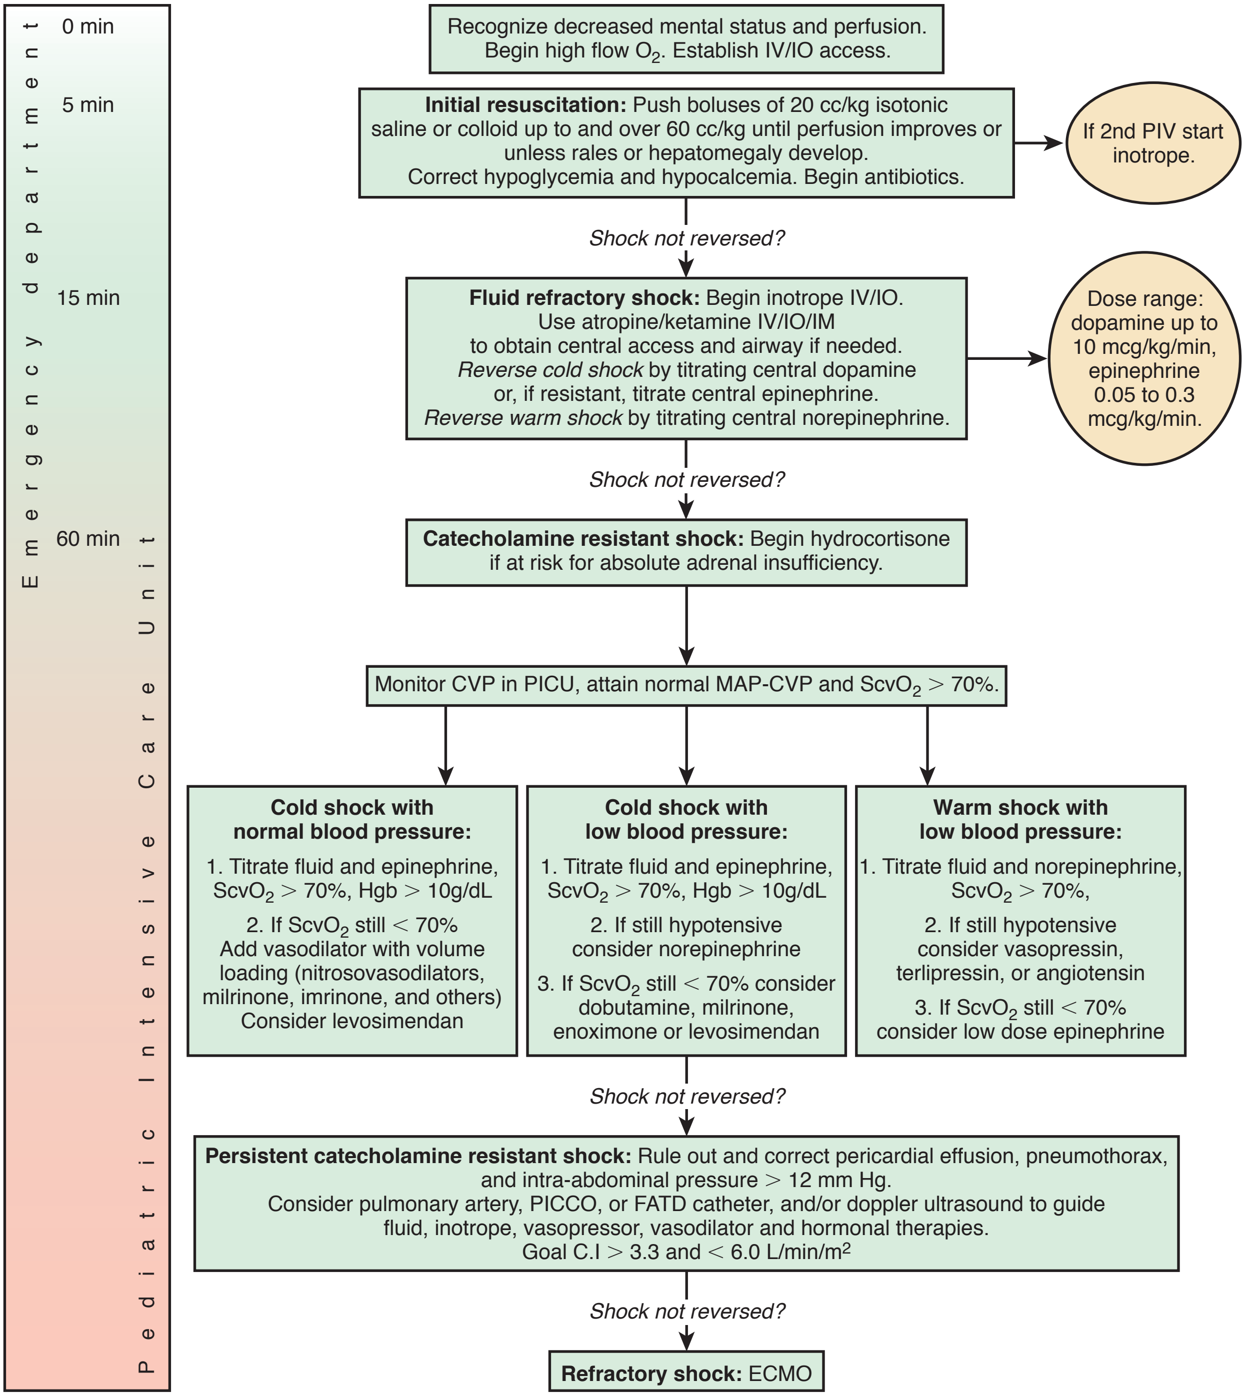

Figure 70-1 **Algorithm for time-sensitive, goal-directed, stepwise management of hemodynamic support in infants and children.** CI, cardiac index; CRRT, continuous renal replacement therapy; CVP, central venous pressure; ECMO, extracorporeal membrane oxygenation; FATD, femoral arterial thermodilution; Hgb, hemoglobin; IM, intramuscular; IO, intraosseous; IV, intravenous; MAP, mean arterial pressure; PICCO, pulse contour cardiac output. *(From Brierly J, Carcillo JA, Choong K, et al: Clinical practice parameters for hemodynamic support of pediatric and neonatal septic shock: 2007 update from the American College of Critical Care Medicine,* Crit Care Med *37:666-688, 2009. PATHOPHYSIOLOGY

An initial insult triggers shock, leading to inadequate oxygen delivery to organs and tissues. Compensatory mechanisms attempt to maintain blood pressure by increasing cardiac output and systemic vascular resistance (SVR). The body also attempts to optimize oxygen delivery to the tissues by increasing oxygen extraction and redistributing blood flow to the brain, heart, and kidneys at the expense of the skin and gastrointestinal tract. These responses lead to an initial state of **compensated shock,** in which blood pressure is maintained. If treatment is not initiated or is inadequate during this period, **decompensated shock** develops, with hypotension and tissue damage that may lead to **multisystem organ dysfunction** and ultimately death (Fig. 70-2, Tables 70-2 and 70-3).

In the early phases of shock, multiple compensatory physiologic mechanisms act to maintain blood pressure and preserve tissue perfusion and oxygen delivery. Cardiovascular effects include increases in heart rate, stroke volume, and vascular smooth muscle tone, which are regulated through sympathetic nervous system activation and

Table 70-1 Types of Shock

HYPOVOLEMIC	CARDIOGENIC	DISTRIBUTIVE	SEPTIC	OBSTRUCTIVE
Decreased preload secondary to internal or external losses	Cardiac pump failure secondary to poor myocardial function	Abnormalities of vasomotor tone from loss of venous and arterial capacitance	Encompasses multiple forms of shock Hypovolemic: third spacing of fluids into the extracellular, interstitial space Distributive: early shock with decreased afterload Cardiogenic: depression of myocardial function by endotoxins	Decreased cardiac output secondary to direct impediment to right- or left-heart outflow or restriction of all cardiac chambers
POTENTIAL ETIOLOGIES				
Blood loss: hemorrhage; Plasma loss: burns, nephrotic syndrome; Water/electrolyte loss: vomiting, diarrhea	Congenital heart disease Cardiomyopathies: infectious or acquired, dilated or restrictive Ischemia Arrhythmias	Anaphylaxis Neurologic: loss of sympathetic vascular tone secondary to spinal cord or brainstem injury Drugs	Bacterial Viral Fungal (immunocompromised patients are at increased risk)	Tension pneumothorax Pericardial tamponade Pulmonary embolism Anterior mediastinal masses Critical coarctation of the aorta

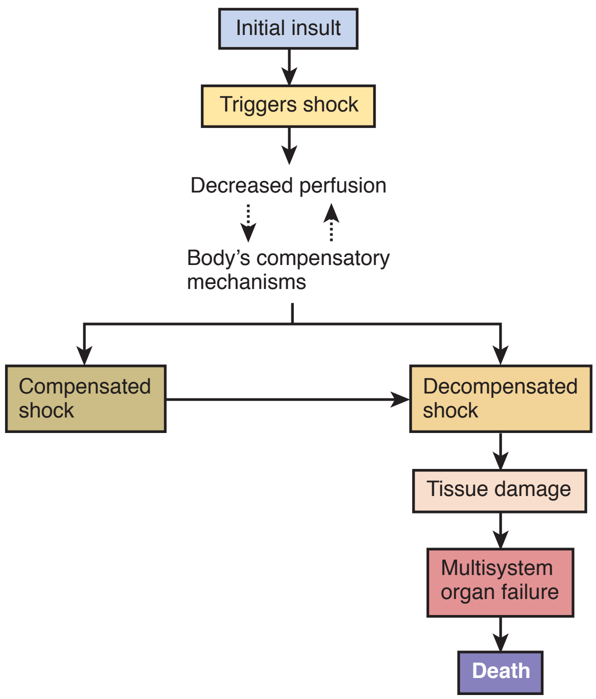

Figure 70-2 Algorithm for decompensated shock.

neurohormonal responses. Respiratory compensation involves greater CO_2 elimination in response to the metabolic acidosis and increased CO_2 production from poor tissue perfusion. Renal excretion of hydrogen ions and retention of bicarbonate also increase in an effort to maintain normal body pH (see Chapter 55.7). Maintenance of intravascular volume is facilitated via sodium regulation through the renin–angiotensin–aldosterone and atrial natriuretic factor axes, cortisol and catecholamine synthesis and release, and antidiuretic hormone secretion. Despite these compensatory mechanisms, the underlying shock and host response lead to vascular endothelial cell injury and significant leakage of intravascular fluids into the interstitial extracellular space.

Another important aspect of the initial pathophysiology of shock is the impact on cardiac output. All forms of shock affect cardiac output via several mechanisms, with changes in heart rate, preload, afterload, and myocardial contractility occurring separately or in combination (Table 70-4). **Hypovolemic shock** is characterized primarily by fluid loss and decreased preload. Tachycardia and an increase in SVR are the initial compensatory responses to maintain cardiac output and systemic blood pressure. Without adequate volume replacement, hypotension develops, followed by tissue ischemia and further clinical deterioration. When there is preexisting low plasma oncotic pressure (caused by nephrotic syndrome, malnutrition, hepatic dysfunction, acute severe burns, etc.), even further volume loss and exacerbation of shock may occur because of endothelial breakdown and worsening capillary leak.

In contrast, the underlying pathophysiologic mechanism leading to **distributive shock** is a state of abnormal vasodilation and decreased SVR. Sepsis, hypoxia, poisonings, anaphylaxis, spinal cord injury, or mitochondrial dysfunction can cause vasodilatory shock (Fig. 70-3). The lowering of SVR is accompanied initially by a maldistribution of blood flow away from vital organs and a compensatory increase in cardiac output. This process leads to significant decreases in both preload and afterload. Therapies for distributive shock must address both of these problems simultaneously.

Cardiogenic shock may be seen in patients with myocarditis, cardiomyopathy, congenital heart disease, or arrhythmias, or following cardiac surgery (see Chapter 434). In these instances, myocardial contractility is affected, leading to systolic and/or diastolic dysfunction. The later phases of all forms of shock frequently have a negative impact on the myocardium, leading to development of a cardiogenic component to the shock state.

Septic shock is often a unique combination of distributive, hypovolemic, and cardiogenic shock. Hypovolemia from intravascular fluid losses occurs through capillary leak. Cardiogenic shock results from the myocardial-depressant effects of sepsis, and distributive shock is the result of decreased SVR. The degree to which a patient exhibits each of these responses varies, but there are frequently alterations in preload, afterload, and myocardial contractility.

In septic shock, it is important to distinguish between the inciting infection and the host inflammatory response. Normally, host immunity prevents the development of sepsis via activation of the reticular endothelial system along with the cellular and humoral immune systems. This host immune response produces an inflammatory cascade of toxic mediators, including hormones, cytokines, and enzymes. If this inflammatory cascade is uncontrolled, derangement of the microcirculatory system leads to subsequent organ and cellular dysfunction.

The **systemic inflammatory response syndrome** (**SIRS**) is an inflammatory cascade that is initiated by the host response to an

Table 70-2 Criteria for Organ Dysfunction

ORGAN SYSTEM	CRITERIA FOR DYSFUNCTION
Cardiovascular	Despite administration of isotonic intravenous fluid bolus ≥60 mL/kg in 1 hr: decrease in BP (hypotension) systolic BP <90 mm Hg, mean arterial pressure <70 mm Hg, <5th percentile for age, or systolic BP <2 SD below normal for age *or* Need for vasoactive drug to maintain BP in normal range (dopamine >5 µg/kg/min or dobutamine, epinephrine, or norepinephrine at any dose) *or* Two of the following: Unexplained metabolic acidosis: base deficit >5.0 mEq/L Increased arterial lactate: >1 mmol/Liter or >2× upper limit of normal Oliguria: urine output <0.5 mL/kg/hr Prolonged capillary refill: >5 sec Core to peripheral temperature gap >3°C (5.4°F)
Respiratory	PaO_2/FIO_2 ratio <300 in absence of cyanotic heart disease or preexisting lung disease *or* $PaCO_2$ >65 torr or 20 mm Hg over baseline $PaCO_2$ *or* Need for >50% FIO_2 to maintain saturation ≥92% *or* Need for nonelective invasive or noninvasive mechanical ventilation
Neurologic	GCS score ≤11 *or* Acute change in mental status with a decrease in GCS score ≥3 points from abnormal baseline
Hematologic	Platelet count <100,000/mm^3 or a decline of 50% in the platelet count from the highest value recorded over the last 3 days (for patients with chronic hematologic or oncologic disorders) *or* INR >1.5 *or* Activated prothrombin time >60 sec
Renal	Serum creatinine >0.5 mg/dL, ≥2× upper limit of normal for age, or 2-fold increase in baseline creatinine value
Hepatic	Total bilirubin ≥4 mg/dL (not applicable for newborn) Alanine transaminase level 2× upper limit of normal for age

infectious or noninfectious trigger (Table 70-5). This inflammatory cascade is triggered when the host defense system does not adequately recognize and/or clear the triggering event. The inflammatory cascade initiated by shock can lead to hypovolemia, cardiac and vascular failure, acute respiratory distress syndrome (ARDS), insulin resistance, decreased cytochrome P450 activity (decreased steroid synthesis), coagulopathy, and unresolved or secondary infection. Tumor necrosis factor (TNF) and other inflammatory mediators increase vascular permeability, causing diffuse capillary leak, decreased vascular tone, and an imbalance between perfusion and metabolic demands of the tissues. TNF and interleukin (IL)-1 stimulate the release of proinflammatory and antiinflammatory mediators, causing fever and vasodilation. Proinflammatory mediators include IL-6, IL-12, interferon-γ, and macrophage migration inhibitory factor; antiinflammatory cytokines include IL-10, transforming growth factor-β, and IL-4. Arachidonic acid metabolites lead to the development of fever, tachypnea, ventilation–perfusion abnormalities, and lactic acidosis. Nitric oxide, released from the endothelium or inflammatory cells, is a major contributor to hypotension. Myocardial depression is caused directly by myocardial-depressant factors, TNF, and some interleukins, and further depressed via depleted catecholamines, increased β-endorphin, and production of myocardial nitric oxide.

The inflammatory cascade (Fig. 70-4) is initiated by toxins or superantigens via macrophage binding or lymphocyte activation. The vascular endothelium is both a target of tissue injury and a source

Table 70-4 Pathophysiology of Shock

EXTRACORPOREAL FLUID LOSS Hypovolemic shock may be a result of direct blood loss through hemorrhage or abnormal loss of body fluids (diarrhea, vomiting, burns, diabetes mellitus or insipidus, nephrosis)
LOWERING PLASMA ONCOTIC FORCES Hypovolemic shock may also result from hypoproteinemia (liver injury, or as a progressive complication of increased capillary permeability)
ABNORMAL VASODILATION Distributive shock (neurogenic, anaphylaxis, or septic shock) occurs when there is loss of vascular tone—venous, arterial, or both (sympathetic blockade, local substances affecting permeability, acidosis, drug effects, spinal cord transection)
INCREASED VASCULAR PERMEABILITY Sepsis may change the capillary permeability in the absence of any change in capillary hydrostatic pressure (endotoxins from sepsis, excess histamine release in anaphylaxis)
CARDIAC DYSFUNCTION Peripheral hypoperfusion may result from any condition that affects the heart's ability to pump blood efficiently (ischemia, acidosis, drugs, constrictive pericarditis, pancreatitis, sepsis)

Table 70-3 Signs of Decreased Perfusion

ORGAN SYSTEM	↓ PERFUSION	↓↓ PERFUSION	↓↓↓ PERFUSION
Central nervous system	—	Restless, apathetic, anxious	Agitated/confused, stuporous, coma
Respiration	—	↑ Ventilation	↑↑ Ventilation
Metabolism	—	Compensated metabolic acidemia	Uncompensated metabolic acidemia
Gut	—	↓ Motility	Ileus
Kidney	↓ Urine volume ↑ Urinary specific gravity	Oliguria (<0.5 mL/kg/hr)	Oliguria/anuria
Skin	Delayed capillary refill	Cool extremities	Mottled, cyanotic, cold extremities
Cardiovascular system	↑ Heart rate	↑↑ Heart rate ↓ Peripheral pulses	↑↑ Heart rate ↓ Blood pressure, central pulses only

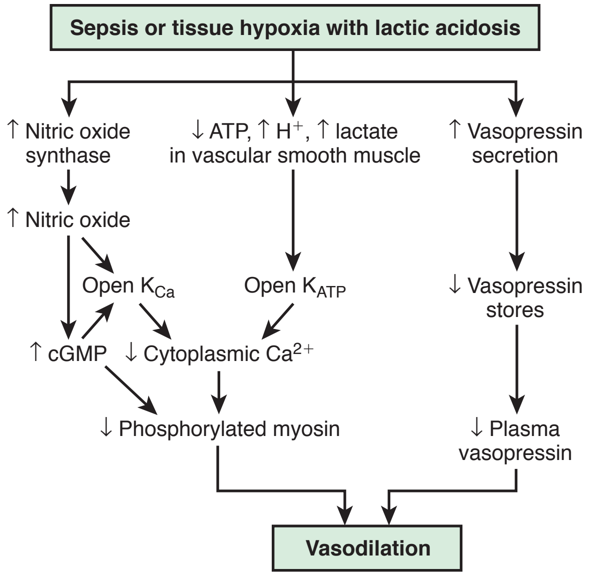

Figure 70-3 **Mechanisms of vasodilatory shock.** Septic shock and states of prolonged shock causing tissue hypoxia with lactic acidosis increase nitric oxide synthesis, activate the adenosine triphosphate (ATP)–sensitive and calcium-regulated potassium channels (K_{ATP} and K_{Ca}, respectively) in vascular smooth muscle, and lead to depletion of vasopressin. cGMP, cyclic guanosine monophosphate. *(From Landry DW, Oliver JA: The pathogenesis of vasodilatory shock,* N Engl J Med *345:588-595, 2001.)*

of mediators that may cause further injury. Biochemical responses include the production of arachidonic acid metabolites, release of myocardial depressant factors, release of endogenous opiates, activation of the complement system, as well as the production and release of many other mediators, which may be either proinflammatory or antiinflammatory. The balance between these mediator groups for an individual patient contributes to the progression of disease and affects the chance for survival.

CLINICAL MANIFESTATIONS

Table 70-1 shows a classification system for shock. Categorization is important, but there may be significant overlap among these groups, especially in septic shock. The clinical presentation of shock depends in part on the underlying etiology, but if unrecognized and untreated, all forms of shock follow a common and untoward progression of clinical signs and pathophysiologic changes that may ultimately lead to irreversible organ injury and death (see Fig. 70-2).

Shock may initially manifest as only tachycardia, with or without tachypnea. Progression leads to decreased urine output, poor peripheral perfusion, respiratory distress or failure, alteration of mental status, and low blood pressure (see Table 70-3). A significant misconception is that shock occurs only with low blood pressure; hypotension is often a late finding and is not a criterion for the diagnosis of shock because of a complex set of compensatory mechanisms attempting to preserve blood pressure. Hypotension reflects an advanced state of decompensated shock and is associated with increased morbidity and mortality.

Hypovolemic shock often manifests initially as orthostatic hypotension and is associated with dry mucous membranes, dry axillae, poor skin turgor, and decreased urine output. Depending on the degree of dehydration, the patient with hypovolemic shock may present with either normal or slightly cool distal extremities, and pulses may be normal, decreased, or absent depending on disease severity. The presenting signs of **cardiogenic shock** are tachypnea, cool extremities, delayed capillary filling time, poor peripheral and/or central pulses, declining mental status, and decreased urine output, caused by the combination of decreased cardiac output and compensatory peripheral

Table 70-5	Differential Diagnosis of Systemic Inflammatory Response Syndrome

INFECTION
Bacteremia or meningitis (*Streptococcus pneumoniae, Haemophilus influenzae* type b, *Neisseria meningitidis,* group A streptococcus, *Staphylococcus aureus*)
Viral illness (influenza, enteroviruses, hemorrhagic fever group, herpes simplex virus, respiratory syncytial virus, cytomegalovirus, Epstein-Barr virus)
Encephalitis (arboviruses, enteroviruses, herpes simplex virus)
Rickettsiae (Rocky Mountain spotted fever, *Ehrlichia,* Q fever)
Syphilis
Vaccine reaction (pertussis, influenza, measles)
Toxin-mediated reaction (toxic shock, staphylococcal scalded skin syndrome)

CARDIOPULMONARY
Pneumonia (bacteria, virus, mycobacteria, fungi, allergic reaction)
Pulmonary emboli
Heart failure
Arrhythmia
Pericarditis
Myocarditis

METABOLIC-ENDOCRINE
Adrenal insufficiency (adrenogenital syndrome, Addison disease, corticosteroid withdrawal)
Electrolyte disturbances (hyponatremia or hypernatremia; hypocalcemia or hypercalcemia)
Diabetes insipidus
Diabetes mellitus
Inborn errors of metabolism (organic acidosis, urea cycle, carnitine deficiency, mitochondrial disorders)
Hypoglycemia
Reye syndrome

GASTROINTESTINAL

Toxic envenomation
Macrophage activation syndrome

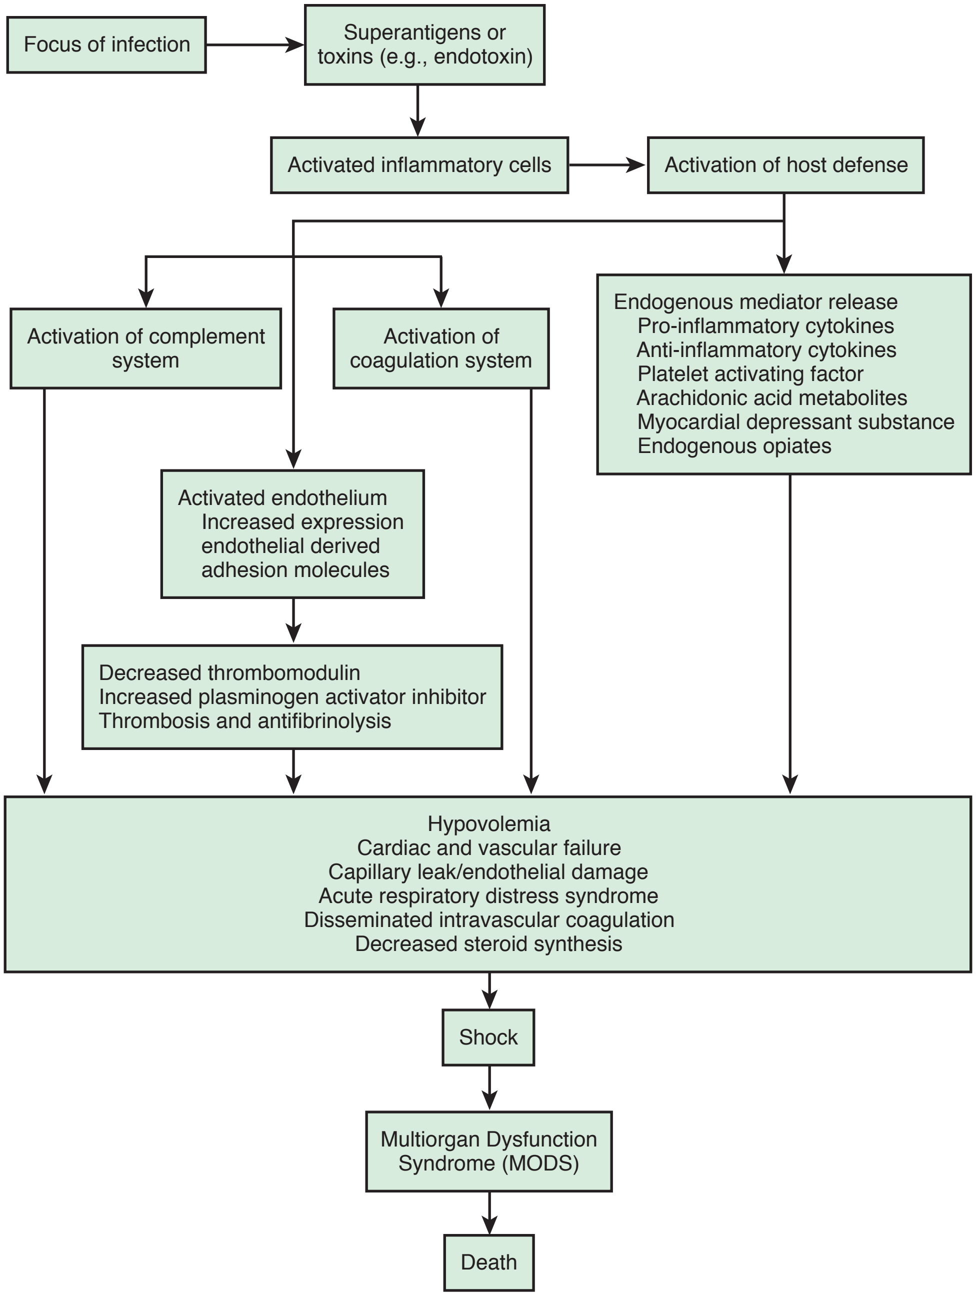

Figure 70-4 Hypothetical pathophysiology of the septic process.

vasoconstriction (see Chapter 442.1). **Obstructive shock** often also manifests as inadequate cardiac output because of a physical restriction of forward blood flow, and the acute presentation may quickly progress to cardiac arrest. **Distributive shock** manifests initially as peripheral vasodilation and increased but inadequate cardiac output.

Regardless of etiology, uncompensated shock, with hypotension, high SVR, decreased cardiac output, respiratory failure, obtundation, and oliguria, occurs late in the progression of disease. Table 70-6 lists the hemodynamic findings in various shock states. Additional clinical findings in shock include cutaneous lesions such as petechiae, diffuse erythema, ecchymoses, ecthyma gangrenosum, and peripheral gangrene. Jaundice can be present either as a sign of infection or as a result of **MODS**.

Sepsis is defined as **SIRS** resulting from a suspected or proven infectious etiology. The clinical spectrum of sepsis begins when a systemic (e.g., bacteremia, rickettsial disease, fungemia, viremia) or localized (e.g., meningitis, pneumonia, pyelonephritis) infection progresses from sepsis to **severe sepsis** (the presence of sepsis combined with organ dysfunction). Further deterioration leads to **septic shock** (severe sepsis plus the persistence of hypoperfusion or hypotension despite adequate fluid resuscitation or a requirement for vasoactive agents), **MODS**, and possibly death (Table 70-7). This is a complex spectrum of clinical problems that is a leading cause of mortality in children worldwide. This mortality can be mitigated and outcomes improved with early recognition and treatment.

Although **septic shock** is primarily distributive in nature, multiple other elements of pathophysiology are represented in this disease process. The initial signs and symptoms of sepsis include alterations in temperature regulation (hyperthermia or hypothermia), tachycardia, and tachypnea. In the early stages (hyperdynamic phase, low SVR, or "warm" shock), cardiac output increases in an attempt to maintain adequate oxygen delivery and meet the greater metabolic demands of the organs and tissues. As septic shock progresses, cardiac output falls in response to the effects of numerous inflammatory mediators, leading to a compensatory elevation in SVR and the development of "cold" shock.

Table 70-7 International Consensus Definitions for Pediatric Sepsis

Infection	Suspected or proven infection or a clinical syndrome associated with high probability of infection
SIRS	Two of 4 criteria, 1 of which must be abnormal temperature or abnormal leukocyte count: 1. Core temperature >38.5°C (101.3°F) or <36°C (96.8°F) (rectal, bladder, oral, or central catheter) 2. Tachycardia: Mean heart rate >2 SD above normal for age in absence of external stimuli, chronic drugs or painful stimuli *or* Unexplained persistent elevation over 0.5-4 hr *or* In children <1 yr old, persistent bradycardia over 0.5 hr (mean heart rate <10th percentile for age in absence of vagal stimuli, β-blocker drugs, or congenital heart disease) 3. Respiratory rate >2 SD above normal for age or acute need for mechanical ventilation not related to neuromuscular disease or general anesthesia 4. Leukocyte count elevated or depressed for age (not secondary to chemotherapy) or >10% immature neutrophils
Sepsis	SIRS plus a suspected or proven infection
Severe sepsis	Sepsis plus 1 of the following: 1. Cardiovascular organ dysfunction, defined as: • Despite >40 mL/kg of isotonic intravenous fluid in 1 hr: • Hypotension <5th percentile for age or systolic blood pressure <2 SD below normal for age *or* • Need for vasoactive drug to maintain blood pressure *or* • 2 of the following: • Unexplained metabolic acidosis: base deficit >5 mEq/L • Increased arterial lactate: >2 times upper limit of normal • Oliguria: urine output <0.5 mL/kg/hr • Prolonged capillary refill: >5 sec • Core to peripheral temperature gap >3°C (5.4°F) 2. ARDS as defined by the presence of a PaO_2/FIO_2 ratio ≤300 mm Hg, bilateral infiltrates on chest radiograph, and no evidence of left heart failure or Sepsis plus 2 or more organ dysfunctions (respiratory, renal, neurologic, hematologic, or hepatic)
Septic shock	Sepsis plus cardiovascular organ dysfunction as defined above
MODS	Presence of altered organ function such that homeostasis cannot be maintained without medical intervention

FIO_2, fraction of inspired oxygen; PaO_2, partial pressure arterial oxygen.

DIAGNOSIS

Shock is a clinical diagnosis based on a thorough history and physical examination (see Tables 70-2 and 70-3). Of note, septic shock has a specific consensus conference definition (see Table 70-7). In cases of suspected septic shock, an infectious etiology should be sought through culture of clinically appropriate specimens and prompt initiation of empiric antimicrobial therapy based on patient age, underlying disease, and geographic location, recognizing that time is necessary for incubation of cultures, and results often are not positive. Additional evidence for identifying an infectious etiology as the cause of SIRS includes physical examination findings, imaging, presence of white blood cells in normally sterile body fluids, and suggestive rashes such as petechiae and purpura. Affected children should be admitted to an intensive care unit or other highly monitored environment, as indicated by clinical status and the resources of the medical facility. These patients necessitate continuous monitoring, with a combination of

noninvasive (pulse oximetry, capnography, near infra-red spectroscopy) and invasive (central venous pressure, arterial blood pressure) techniques as clinically indicated.

LABORATORY FINDINGS

Laboratory findings often include evidence of hematologic abnormalities and electrolyte disturbances. Hematologic abnormalities may include thrombocytopenia, prolonged prothrombin and partial thromboplastin times, reduced serum fibrinogen level, elevations of fibrin split products, and anemia. Elevated neutrophil counts and increased immature forms (i.e., bands, myelocytes, promyelocytes), vacuolation of neutrophils, toxic granulations, and Döhle bodies can be seen with infection. Neutropenia or leukopenia may be an ominous sign of overwhelming sepsis.

Glucose dysregulation, a common stress response, may manifest as hyperglycemia or hypoglycemia. Other electrolyte abnormalities are hypocalcemia, hypoalbuminemia, and metabolic acidosis. Renal and/or hepatic function may also be abnormal. Patients with ARDS or pneumonia have impairment of oxygenation (decreased partial pressure arterial oxygen [Pao_2]) as well as of ventilation (increased arterial partial pressure of carbon dioxide [$Paco_2$]) in the later stages of lung injury (see Chapter 71).

The hallmark of uncompensated shock is an imbalance between oxygen delivery (Do_2) and oxygen consumption (Vo_2). Oxygen delivery normally exceeds oxygen consumption threefold. The oxygen extraction ratio is approximately 25%, thus producing a normal **mixed venous oxygen saturation** (SVo_2) of 75-80%. A falling SVo_2 value, as measured by cooximetry, reflects an increasing oxygen extraction ratio and documents a decrease in oxygen delivery relative to consumption. This increase in oxygen extraction by the end-organs is an attempt to maintain adequate oxygen delivery at the cellular level. This state is manifested clinically by increased lactic acid production (high anion gap, metabolic acidosis) caused by anaerobic metabolism and the compensatory increase in tissue oxygen extraction. The gold standard measurement of SVo_2 is from a pulmonary arterial catheter, but measurements from this location are often not clinically feasible. Sites such as the right ventricle, right atrium, superior vena cava ($SVco_2$), or inferior vena cava are often used as for surrogate measures of mixed venous blood to follow the adequacy of oxygen delivery and effectiveness of therapeutic interventions. *Elevated blood lactate levels reflect poor tissue oxygen delivery noted in all forms of shock.*

TREATMENT

Initial Management

Early recognition and prompt intervention are extremely important in the management of all forms of shock (Tables 70-8 to 70-12). **(The vital sign targets and dose recommendations in Tables 70-9 to 70-11 should be adjusted to pediatric-size patients).** Baseline mortality is much lower in pediatric shock than in adult shock, and further improvements in mortality are associated with early interventions (see Fig. 70-1). The initial assessment and treatment of the pediatric shock patient should include stabilization of airway, breathing, and circulation as established by the American Heart Association's pediatric advanced life support and neonatal advanced life support guidelines (see Chapter 67). Depending on the severity of shock, further airway intervention, including intubation and mechanical ventilation, may be necessary to lessen the work of breathing and decrease the body's overall metabolic demands.

Given the predominance of sepsis and hypovolemia as the most common causes of shock in the pediatric population, most therapeutic regimens are based on guidelines established in these settings. Immediately following establishment of intravenous (IV) or intraosseous

Table 70-8 Goal-Directed Therapy of Organ System Dysfunction in Shock

SYSTEM	DISORDERS	GOALS	THERAPIES
Respiratory	Acute respiratory distress syndrome Respiratory muscle fatigue Central apnea	Prevent/treat: hypoxia and respiratory acidosis Prevent barotrauma Decrease work of breathing	Oxygen Noninvasive ventilation Early endotracheal intubation and mechanical ventilation Positive end-expiratory pressure (PEEP) Permissive hypercapnia High-frequency ventilation Extracorporeal membrane oxygenation (ECMO)
Renal	Prerenal failure Renal failure	Prevent/treat: hypovolemia, hypervolemia, hyperkalemia, metabolic acidosis, hypernatremia/hyponatremia, and hypertension Monitor serum electrolytes	Judicious fluid resuscitation Establishment of normal urine output and blood pressure for age Furosemide (Lasix) Dialysis, ultrafiltration, hemofiltration
Hematologic	Coagulopathy (disseminated intravascular coagulation) Thrombosis	Prevent/treat: bleeding Prevent/treat: abnormal clotting	Vitamin K Fresh-frozen plasma Platelets Heparinization
Gastrointestinal	Stress ulcers Ileus Bacterial translocation	Prevent/treat: gastric bleeding Avoid aspiration, abdominal distention Avoid mucosal atrophy	Histamine H_2-receptor–blocking agents or proton pump inhibitors Nasogastric tube Early enteral feedings
Endocrine	Adrenal insufficiency, primary or secondary to chronic steroid therapy	Prevent/treat: adrenal crisis	Stress-dose steroids in patients previously given steroids Physiologic dose for presumed primary insufficiency in sepsis
Metabolic	Metabolic acidosis	Correct etiology Normalize pH	Treatment of hypovolemia (fluids), poor cardiac function (fluids, inotropic agents) Improvement of renal acid excretion Low-dose (0.5-2.0 mEq/kg) sodium bicarbonate if the patient is not showing response, pH <7.1, and ventilation (CO_2 elimination) is adequate

Table 70-9 Recommendations: Initial Resuscitation and Infection Issues—Adults

INITIAL RESUSCITATION

1. Protocolized, quantitative resuscitation of patients with sepsis-induced tissue hypoperfusion (defined in this document as hypotension persisting after initial fluid challenge or blood lactate concentration ≥4 mmol/L). Goals during the 1st 6 hr of resuscitation:
   (a) Central venous pressure 8-12 mm Hg
   (b) Mean arterial pressure (MAP) ≥65 mm Hg
   (c) Urine output ≥0.5 mL kg^{-1} hr
   (d) Central venous (superior vena cava) or mixed venous oxygen saturation 70% or 65%, respectively
2. In patients with elevated lactate levels, targeting resuscitation to normalize lactate as rapidly as possible.

SCREENING FOR SEPSIS AND PERFORMANCE IMPROVEMENT

1. Routine screening of potentially infected seriously ill patients for severe sepsis to allow earlier implementation of therapy.
2. Hospital-based performance improvement efforts in severe sepsis.

DIAGNOSIS

1. Cultures as clinically appropriate before antimicrobial therapy if no significant delay (>45 min) in the start of antimicrobial(s). At least 2 sets of blood cultures (both aerobic and anaerobic bottles) be obtained before antimicrobial therapy with at least 1 drawn percutaneously and 1 drawn through each vascular access device, unless the device was recently (<48 hr) inserted.
2. Use of the 1,3 β-D-glucan assay, mannan and antimannan antibody assays, if available and invasive candidiasis is in differential diagnosis of cause of infection.
3. Imaging studies performed promptly to confirm a potential source of infection.

ANTIMICROBIAL THERAPY

1\. Administration of effective intravenous antimicrobials within the first hour of recognition of septic shock and severe sepsis without septic shock as the goal of therapy.
2a. Initial empiric antiinfective therapy of one or more drugs that have activity against all likely pathogens (bacterial and/or fungal or viral) and that penetrate in adequate concentrations into tissues presumed to be the source of sepsis.
2b. Antimicrobial regimen should be reassessed daily for potential deescalation.
3\. Use of low procalcitonin levels or similar biomarkers to assist the clinician in the discontinuation of empiric antibiotics in patients who initially appeared septic, but have no subsequent evidence of infection.
4a. Combination empirical therapy for neutropenic patients with severe sepsis and for patients with difficult to treat, multidrug-resistant bacterial pathogens such as *Acinetobacter* and *Pseudomonas* spp.
For patients with severe infections associated with respiratory failure and septic shock, combination therapy with an extended spectrum β-lactam and either an aminoglycoside or a fluoroquinolone is for *Pseudomonas aeruginosa* bacteremia. A combination of beta-lactam and macrolide for patients with septic shock from bacteremic *Streptococcus pneumoniae* infections.
4b. Empiric combination therapy should not be administered for more than 3-5 days. Deescalation to the most appropriate single therapy should be performed as soon as the susceptibility profile is known.
5\. Duration of therapy typically 7-10 days; longer courses may be appropriate in patients who have a slow clinical response, undrainable foci of infection, bacteremia with *Staphylococcus aureus*; some fungal and viral infections or immunologic deficiencies, including neutropenia.
6\. Antiviral therapy initiated as early as possible in patients with severe sepsis or septic shock of viral origin.
7\. Antimicrobial agents should not be used in patients with severe inflammatory states determined to be of noninfectious cause.

SOURCE CONTROL

1. A specific anatomical diagnosis of infection requiring consideration for emergent source control be sought and diagnosed or excluded as rapidly as possible, and intervention be undertaken for source control within the 1st 12 hr after the diagnosis is made, if feasible.
2. When infected peripancreatic necrosis is identified as a potential source of infection, definitive intervention is best delayed until adequate demarcation of viable and nonviable tissues has occurred.
3. When source control in a severely septic patient is required, the effective intervention associated with the least physiologic insult should be used (e.g., percutaneous rather than surgical drainage of an abscess).
4. If intravascular access devices are a possible source of severe sepsis or septic shock, they should be removed promptly after other vascular access has been established.

INFECTION PREVENTION

1a. Selective oral decontamination and selective digestive decontamination should be introduced and investigated as a method to reduce the incidence of ventilator-associated pneumonia; this infection control measure can then be instituted in healthcare settings and regions where this methodology is found to be effective.
1b. Oral chlorhexidine gluconate be used as a form of oropharyngeal decontamination to reduce the risk of ventilator-associated pneumonia in ICU patients with severe sepsis.

Adapted from Dellinger PR, Levy MM, Rhodes A, et al: Surviving sepsis campaign: International guidelines for management of severe sepsis and septic shock: 2012. Crit Care Med 41(2):580-637, 2013, Table 5, p. 589.

access, aggressive, early goal-directed therapy should be initiated unless there are significant concerns for cardiogenic shock as an underlying pathophysiology. Rapid IV administration of 20 mL/kg isotonic fluid should be initiated in an attempt to reverse the shock state. This bolus should be repeated quickly up to 60-80 mL/kg; it is not unusual for severely affected patients to require this volume within the 1st hr of treatment.

Rapid fluid resuscitation totaling 60-80 mL/kg or more is associated with improved survival without an increased incidence of pulmonary edema. Fluid resuscitation in increments of 20 mL/kg should be titrated to normalize heart rate (according to age-based heart rates), urine output (to 1 mL/kg/hr), capillary refill time (to <2 sec), and mental status. Fluid resuscitation may sometimes require as much as 200 mL/kg or greater. It must be stressed that hypotension is often a late and ominous finding, and normalization of blood pressure alone is not a reliable endpoint for assessing the effectiveness of resuscitation. Although the type of fluid (crystalloid vs. colloid) is an area of ongoing debate, fluid resuscitation (usually crystalloid) in the 1st hr is unquestionably essential to survival in septic shock, regardless of the fluid type administered.

In one study conducted in Kenya and Tanzania, routine bolus fluid resuscitation of severely ill, febrile children with poor perfusion was unexpectedly associated with a higher mortality than children receiving nonbolus intravenous infusions. The children in this study had a

Table 70-10 Surviving Sepsis Campaign Care Bundles

To be completed within 3 hr:
1. Measure lactate level
2. Obtain blood cultures prior to administration of antibiotics
3. Administer broad spectrum antibiotics
4. Administer 30 mL/kg crystalloid for hypotension or lactate ≥4 mmol/L

To completed within 6 hr:
5. Apply vasopressors (for hypotension that does not respond to initial fluid resuscitation) to maintain a mean arterial pressure (MAP) ≥65 mm Hg
6. In the event of persistent arterial hypotension despite volume resuscitation (septic shock) or initial lactate ≥4 mmol/L (36 mg/dL):
   Measure central venous pressure (CVP)*
   Measure central venous oxygen saturation ($ScvO_2$)*
7. Remeasure lactate if initial lactate was elevated*

*Targets for quantitative resuscitation included in the guidelines are CVP of ≥8 mm Hg, $ScvO_2$ of ≥70%, and normalization of lactate.

Adapted from Dellinger PR, Levy MM, Rhodes A, et al: Surviving sepsis campaign: International guidelines for management of severe sepsis and septic shock: 2012. Crit Care Med *41(2):580-637, 2013, Fig. 1, p. 591.*

high incidence of malaria, severe anemia, hypoxia, and coma; most were thought to have bacterial infections. There were no children with dengue shock syndrome or hypovolemia secondary to gastroenteritis. The World Health Organization's definition of shock that requires fluid boluses (cold hands, capillary refill >3 sec, fast and weak pulses) was not present in all patients; only 6% had hypotension. This study raises issues about bolus fluid resuscitation in resource poor areas, particularly in children with a high prevalence of malaria and anemia.

If shock remains refractory following 60-80 mL/kg of volume resuscitation, vasopressor therapy (norepinephrine, or epinephrine) should be instituted while additional fluids are administered. Current guidelines recommend administration of these vasoactive agents via peripheral intravenous lines, with very close monitoring of the peripheral intravenous sites while central venous access is being obtained based on data demonstrating that delay in the initiation of inotropes in shock is associated with increased mortality

Additional Early Considerations

In **septic shock** specifically, early administration of broad-spectrum antimicrobial agents is associated with a reduction in mortality. The choice of antimicrobial agents depends on the predisposing risk factors and the clinical situation. Bacterial resistance patterns in the community and/or hospital should be considered in the selection of optimal antimicrobial therapy. Neonates should be treated with ampicillin

Table 70-11 Recommendations: Hemodynamic Support and Adjunctive Therapy—Adults

FLUID THERAPY OF SEVERE SEPSIS
1. Crystalloids as the initial fluid of choice in the resuscitation of severe sepsis and septic shock.
2. Against the use of hydroxyethyl starches for fluid resuscitation of severe sepsis and septic shock.
3. Albumin in the fluid resuscitation of severe sepsis and septic shock when patients require substantial amounts of crystalloids.
4. Initial fluid challenge in patients with sepsis-induced tissue hypoperfusion with suspicion of hypovolemia to achieve a minimum of 30 mL/kg of crystalloids (a portion of this may be albumin equivalent). More rapid administration and greater amounts of fluid may be needed in some patients.
5. Fluid challenge technique be applied wherein fluid administration is continued as long as there is hemodynamic improvement either based on dynamic (e.g., change in pulse pressure, stroke volume variation) or static (e.g., arterial pressure, heart rate) variables.

VASOPRESSORS
1. Vasopressor therapy initially to target a mean arterial pressure (MAP) of 65 mm Hg.
2. Norepinephrine as the first choice vasopressor.
3. Epinephrine (added to and potentially substituted for norepinephrine) when an additional agent is needed to maintain adequate blood pressure.
4. Vasopressin 0.03 units/min can be added to norepinephrine (NE) with intent of either raising MAP or decreasing NE dosage.
5. Low-dose vasopressin is not recommended as the single initial vasopressor for treatment of sepsis-induced hypotension and vasopressin doses higher than 0.03-0.04 units/min should be reserved for salvage therapy (failure to achieve adequate MAP with other vasopressor agents).
6. Dopamine as an alternative vasopressor agent to norepinephrine only in highly selected patients (e.g., patients with low risk of tachyarrhythmias and absolute or relative bradycardia).
7. Phenylephrine is not recommended in the treatment of septic shock except in circumstances where (a) NE is associated with serious arrhythmias, (b) cardiac output is known to be high and blood pressure persistently low, or (c) as salvage therapy when combined inotrope/vasopressor drugs and low-dose vasopressin have failed to achieve MAP target.
8. Low-dose dopamine should not be used for renal protection.
9. All patients requiring vasopressors have an arterial catheter placed as soon as practical if resources are available.

INOTROPIC THERAPY
1. A trial of dobutamine infusion up to 20 μg/kg/min be administered or added to vasopressor (if in use) in the presence of (a) myocardial dysfunction as suggested by elevated cardiac filling pressures and low cardiac output, or (b) ongoing signs of hypoperfusion, despite achieving adequate intravascular volume and adequate MAP.
2. Not using a strategy to increase cardiac index to predetermined supranormal levels.

CORTICOSTEROIDS
1. Not using intravenous hydrocortisone to treat adult septic shock patients if adequate fluid resuscitation and vasopressor therapy are able to restore hemodynamic stability (see goals for Initial Resuscitation). In case this is not achievable, we suggest intravenous hydrocortisone alone at a dose of 200 mg per day.
2. Not using the ACTH stimulation test to identify adults with septic shock who should receive hydrocortisone.
3. In treated patients, hydrocortisone tapered when vasopressors are no longer required.
4. Corticosteroids should not be administered for the treatment of sepsis in the absence of shock.
5. When hydrocortisone is given, use continuous flow.

Adapted from Dellinger PR, Levy MM, Rhodes A, et al: Surviving sepsis campaign: International guidelines for management of severe sepsis and septic shock: 2012. Crit Care Med *41(2):580-637, 2013, Table 6, p. 596.*

Table 70-12 Recommendations: Special Considerations in Pediatrics

INITIAL RESUSCITATION
1. For respiratory distress and hypoxemia start with face mask oxygen or if needed and available, high flow nasal cannula oxygen or nasopharyngeal CPAP (NP CPAP). For improved circulation, peripheral intravenous access or intraosseous access can be used for fluid resuscitation and inotrope infusion when a central line is not available. If mechanical ventilation is required then cardiovascular instability during intubation is less likely after appropriate cardiovascular resuscitation.
2. Initial therapeutic end points of resuscitation of septic shock: capillary refill of ≤2 sec, normal blood pressure for age, normal pulses with no differential between peripheral and central pulses, warm extremities, urine output >1 mL kg^{-1} hr^{-1}, and normal mental status. $ScvO_2$ saturation ≥70% and cardiac index between 3.3 and 6.0 L/min/m^2 should be targeted thereafter.
3. Follow American College of Critical Care Medicine-Pediatric Life Support (ACCM-PALS) guidelines for the management of septic shock.
4. Evaluate for and reverse pneumothorax, pericardial tamponade, or endocrine emergencies in patients with refractory shock.

ANTIBIOTICS AND SOURCE CONTROL
1. Empiric antibiotics should be administered within 1 hr of the identification of severe sepsis. Blood cultures should be obtained before administering antibiotics when possible but this should not delay administration of antibiotics. The empiric drug choice should be changed as epidemic and endemic ecologies dictate (e.g., H1N1, methicillin-resistant *Staphylococcus aureus* [MRSA], chloroquine-resistant malaria, penicillin-resistant pneumococci, recent ICU stay, neutropenia).
2. Clindamycin and antitoxin therapies for toxic shock syndromes with refractory hypotension.
3. Early and aggressive source control.
4. *Clostridium difficile* colitis should be treated with enteral antibiotics if tolerated. Oral vancomycin is preferred for severe disease.

FLUID RESUSCITATION
1. In the industrialized world with access to inotropes and mechanical ventilation, initial resuscitation of hypovolemic shock begins with infusion of isotonic crystalloids or albumin with boluses of up to 20 mL/kg crystalloids (or albumin equivalent) over 5-10 minutes, titrated to reversing hypotension, increasing urine output, and attaining normal capillary refill, peripheral pulses, and level of consciousness without inducing hepatomegaly or rales. If hepatomegaly or rales exist then inotropic support should be implemented, not fluid resuscitation. In nonhypotensive children with severe hemolytic anemia (severe malaria or sickle cell crises), blood transfusion is considered superior to crystalloid or albumin bolus.

INOTROPES/VASOPRESSORS/VASODILATORS
1. Begin peripheral inotropic support until central venous access can be attained in children who are not responsive to fluid resuscitation.
2. Patients with low cardiac output and elevated systemic vascular resistance states with normal blood pressure should be given vasodilator therapies in addition to inotropes.

EXTRACORPOREAL MEMBRANE OXYGENATION (ECMO)
1. Consider ECMO for refractory pediatric septic shock and respiratory failure.

CORTICOSTEROIDS
1. Timely hydrocortisone therapy in children with fluid refractory, catecholamine resistant shock and suspected or proven absolute (classic) adrenal insufficiency.

PROTEIN C AND ACTIVATED PROTEIN CONCENTRATE
No recommendation as no longer available.

BLOOD PRODUCTS AND PLASMA THERAPIES
1. Similar hemoglobin targets in children as in adults. During resuscitation of low superior vena cava oxygen saturation shock (<70 %), hemoglobin levels of 10 g/dL are targeted. After stabilization and recovery from shock and hypoxemia, a lower target (>7.0 g/dL) can be considered reasonable.
2. Similar platelet transfusion targets in children as in adults.
3. Use plasma therapies in children to correct sepsis-induced thrombotic purpura disorders, including progressive disseminated intravascular coagulation, secondary thrombotic microangiopathy, and thrombotic thrombocytopenic purpura.

MECHANICAL VENTILATION
1. Lung-protective strategies during mechanical ventilation.

SEDATION/ANALGESIA/DRUG TOXICITIES
1. We recommend use of sedation with a sedation goal in critically ill mechanically ventilated patients with sepsis.
2. Monitor drug toxicity labs because drug metabolism is reduced during severe sepsis, putting children at greater risk of adverse drug-related events.

GLYCEMIC CONTROL
1. Control hyperglycemia using a similar target as in adults (≤180 mg/dL). Glucose infusion should accompany insulin therapy in newborns and children because some hyperglycemic children make no insulin whereas others are insulin resistant.

DIURETICS AND RENAL REPLACEMENT THERAPY
1. Use diuretics to reverse fluid overload when shock has resolved, and if unsuccessful then continuous venovenous hemofiltration (CVVH) or intermittent dialysis to prevent >10% total body weight fluid overload.

DEEP VEIN THROMBOSIS (DVT) PROPHYLAXIS
No recommendation on the use of DVT prophylaxis in prepubertal children with severe sepsis.

STRESS ULCER (SU) PROPHYLAXIS
No recommendation on the use of SU prophylaxis in prepubertal children with severe sepsis

NUTRITION
1. Enteral nutrition given to children who can be fed enterally, and parenteral feeding in those who cannot (grade 2C).

CPAP, continuous positive airway pressure.

Adapted from Dellinger PR, Levy MM, Rhodes A, et al: Surviving sepsis campaign: International guidelines for management of severe sepsis and septic shock: 2012. Crit Care Med *41(2):580-637, 2013, Table 9, p. 614.*

plus cefotaxime and/or gentamicin. Acyclovir should be added if herpes simplex virus is suspected clinically. In infants and children, community-acquired infections with *Neisseria meningitidis* can initially be treated empirically with a 3rd-generation cephalosporin (ceftriaxone or cefotaxime). *Haemophilus influenzae* infections can be treated empirically with a 3rd-generation cephalosporin (ceftriaxone or cefotaxime). The prevalence of resistant *Streptococcus pneumoniae* requires the addition of vancomycin. Suspicion of community- or hospital-acquired, methicillin-resistant *Staphylococcus aureus* infection warrants coverage with vancomycin, depending on local resistance patterns. If an intraabdominal process is suspected, anaerobic coverage should be included with an agent such as metronidazole, clindamycin, or piperacillin-tazobactam.

Nosocomial sepsis should generally be treated with at least a 3rd- or 4th-generation cephalosporin or a penicillin with an extended Gram-negative spectrum (e.g., piperacillin-tazobactam). An aminoglycoside should be added as the clinical situation warrants. Vancomycin should be added to the regimen if the patient has an indwelling medical device (see Chapter 179), Gram-positive cocci are isolated from the blood, methicillin-resistant *S. aureus* infection is suspected, or as empiric coverage for *S. pneumoniae* in a patient with meningitis. Empirical coverage for fungal infections should be considered for selected immunocompromised patients (see Chapter 178). It should be noted that these are broad, generalized recommendations that must be tailored to the individual clinical scenario and to the local resistance patterns of the community and/or hospital.

Distributive shock that is not secondary to sepsis is caused by a primary abnormality in vascular tone. Cardiac output in affected patients is usually maintained and may initially be supranormal. These patients may benefit temporarily from volume resuscitation, but the early initiation of a vasoconstrictive agent to increase SVR is an important element of clinical care. Patients with spinal cord injury and spinal shock may benefit from either phenylephrine or vasopressin to increase SVR, and epinephrine is the treatment of choice for patients with anaphylaxis (Table 70-13). Epinephrine has peripheral α-adrenergic as well as inotropic effects that may improve the myocardial depression seen with anaphylaxis and its associated inflammatory response (see Chapter 149).

Patients with **cardiogenic shock** have poor cardiac output secondary to systolic and/or diastolic myocardial depression, often with a compensatory elevation in SVR. These patients may show poor response to fluid resuscitation and may decompensate quickly when fluids are administered. Smaller boluses of fluid (5-10 mL/kg) should be given in cardiogenic shock to replace deficits and maintain preload. In any patient with shock whose clinical status deteriorates with fluid resuscitation, a cardiogenic etiology should be considered, and further administration of intravenous fluids should be provided judiciously. Early initiation of myocardial support with epinephrine or dopamine to improve cardiac output is important in this context and early consideration should be given to administration of inodilator, such as milrinone.

Despite adequate cardiac output with the support of inotropic agents, a high SVR with poor peripheral perfusion and acidosis may persist in cardiogenic shock. Therefore, if not already started, milrinone therapy may improve systolic function and decrease SVR without causing a significant increase in heart rate. Furthermore, this agent has the added benefit of enhancing diastolic relaxation. Dobutamine or other vasodilating agents, such as nitroprusside, may also be considered in this setting (Table 70-14). Titration of these agents should target clinical end points, including increased urine output, improved peripheral perfusion, resolution of acidosis, and normalization of mental status. Even though they may be beneficial in other forms of shock, agents that improve blood pressure by increasing SVR, such as norepinephrine and vasopressin, should generally be avoided in patients with cardiogenic shock. These agents may cause further decompensation and potentially precipitate cardiac arrest as a result of the increased afterload and additional work imposed on the myocardium. The combination of inotropic and vasoactive agents must be tailored to the pathophysiology of the individual patient with close and frequent reassessment of the patient's cardiovascular status.

For patients with **obstructive shock**, fluid resuscitation may be briefly temporizing in maintaining cardiac output, but the primary insult must be immediately addressed. Examples of lifesaving therapeutic interventions for such patients are pericardiocentesis for pericardial effusion, pleurocentesis or chest tube placement for pneumothorax, thrombectomy/thrombolysis for pulmonary embolism, and the initiation of a prostaglandin infusion for ductus-dependent cardiac lesions. There is often a "last-drop" phenomenon associated with some obstructive lesions, in that small additional amounts of intravascular volume depletion may lead to a rapid deterioration, including cardiac arrest, if the obstructive lesion is not corrected.

Regardless of the etiology of shock, metabolic status should be meticulously maintained (see Table 70-8). Electrolyte levels should be monitored closely and corrected as needed. Hypoglycemia is common and should be promptly treated. Neonates and infants in particular may have profound glucose dysregulation in association with shock. Glucose levels should be checked routinely and treated appropriately, especially early in the course of illness. Hypocalcemia, which may contribute to myocardial dysfunction, should be treated with a goal of normalizing the ionized calcium concentration. There is no evidence that supranormal calcium levels benefit the myocardium, and hypercalcemia may actually be associated with increased myocardial toxicity.

Adrenal function is another important consideration in shock, and hydrocortisone replacement may be beneficial. Up to 50% of critically ill patients may have absolute or relative adrenal insufficiency. Patients at risk for adrenal insufficiency include those with congenial adrenal hypoplasia, abnormalities of the hypothalamic-pituitary axis, and

Table 70-13 Cardiovascular Drug Treatment of Shock

DRUG	EFFECT(S)	DOSING RANGE	COMMENT(S)
Dopamine	↑ Cardiac contractility Significant peripheral vasoconstriction at >10 µg/kg/min	3-20 µg/kg/min	↑ Risk of arrhythmias at high doses
Epinephrine	↑ Heart rate and ↑ cardiac contractility Potent vasoconstrictor	0.05-3.0 µg/kg/min	May ↓ renal perfusion at high doses ↑ Myocardial O_2 consumption Risk of arrhythmia at high doses
Dobutamine	↑ Cardiac contractility Peripheral vasodilator	1-10 µg/kg/min	—
Norepinephrine	Potent vasoconstriction No significant effect on cardiac contractility	0.05-1.5 µg/kg/min	↑ Blood pressure secondary to ↑ systemic vascular resistance ↑ Left ventricular afterload
Phenylephrine	Potent vasoconstriction	0.5-2.0 µg/kg/min	Can cause sudden hypertension ↑ O_2 consumption

Table 70-14	Vasodilators/Afterload Reducers		
DRUG	**EFFECT(S)**	**DOSING RANGE**	**COMMENT(S)**
Nitroprusside	Vasodilator (mainly arterial)	0.5-4.0 µg/kg/min	Rapid effect Risk of cyanide toxicity with prolonged use (>96 hr)
Nitroglycerin	Vasodilator (mainly venous)	1-20 µg/kg/min	Rapid effect Risk of increased intracranial pressure
Prostaglandin E_1	Vasodilator Maintains an open ductus arteriosus in the newborn with ductal-dependent congenital heart disease	0.01-0.2 µg/kg/min	Can lead to hypotension Risk of apnea
Milrinone	Increased cardiac contractility Improves cardiac diastolic function Peripheral vasodilation	Load 50 µg/kg over 15 min 0.5-1.0 µg/kg/min	Phosphodiesterase inhibitor—slows cyclic adenosine monophosphate breakdown

recent therapy with corticosteroids (including patients with asthma, rheumatic diseases, malignancies, and inflammatory bowel disease). These patients are at high risk for adrenal dysfunction and should receive stress doses of hydrocortisone. Steroids may also be considered in patients with shock that is unresponsive to fluid resuscitation and catecholamines. While there may be a subset of pediatric septic shock patients that benefit from treatment with hydrocortisone, currently available pediatric data do not demonstrate an overall survival benefit in patients with shock treated with hydrocortisone. Determination of baseline cortisol levels prior to steroid administration may be beneficial in guiding therapy, although this idea remains controversial.

Considerations for Continued Therapy

After the 1st hr of therapy and attempts at early reversal of shock, focus on goal-directed endpoints should continue in an intensive care setting (see Fig. 70-1 and Table 70-8). Clinical endpoints serve as global markers for organ perfusion and oxygenation. Laboratory parameters such as SVo_2 (or $ScvO_2$), serum lactate concentration, cardiac index, and hemoglobin serve as adjunctive measures of tissue oxygen delivery. Hemoglobin should be maintained at 10 g/dL, SVo_2 (or $ScvO_2$) >70%, and cardiac index at 3.3-6.0 L/min/m^2 to optimize oxygen delivery in the acute phase of shock. It is important to note that cardiac index is rarely monitored in the clinical setting owing to the limited use of pulmonary artery catheters and the lack of accurate noninvasive cardiac output monitors for infants and children. Blood lactate levels and calculation of base deficit from arterial blood gas values are very useful markers for the adequacy of oxygen delivery. These traditional markers are all indicators of global oxygen utilization and delivery, and there is increasing interest in measures of local tissue oxygenation including near infra-red spectroscopy of the cerebrum, flank, or abdomen.

Respiratory support should be used as clinically appropriate. When shock leads to ARDS requiring mechanical ventilation, lung-protective strategies to keep plateau pressure below 30 cm H_2O and maintain tidal volume at 6 mL/kg have been shown to improve mortality in adult patients (see Chapter 71). These data are extrapolated to pediatric patients because of the lack of definitive pediatric studies in this area. Additionally, after the initial shock state has been reversed, data demonstrate that judicious fluid administration, renal replacement therapy, and fluid removal may also be useful in children with anuria or oliguria and fluid overload (see Chapter 535). Other interventions include correction of coagulopathy with fresh frozen plasma or cryoprecipitate and platelet transfusions as necessary, especially in the presence of active bleeding.

If shock remains refractory despite maximal therapeutic interventions, mechanical support with **extracorporeal membrane oxygenation** or a **ventricular assist device** may be indicated. Extracorporeal membrane oxygenation may be lifesaving in cases of refractory shock regardless of underlying etiology. Similarly, a ventricular assist device may be indicated for refractory cardiogenic shock in the setting of cardiomyopathy or recent cardiac surgery. Systemic anticoagulation, which is required while patients are receiving mechanical support, may be difficult, given the significant coagulopathy often encountered in refractory shock, especially when the underlying etiology is sepsis. Mechanical support in refractory shock poses substantial risks but can improve survival in specific populations of patients.

PROGNOSIS

In septic shock, mortality rates are as low as 3% in previously healthy children and 6-9% in children with chronic illness (compared with 25-30% in adults). With early recognition and therapy, the mortality rate for pediatric shock continues to improve, but shock and MODS remain one of the leading causes of death in infants and children. The risk of death involves a complex interaction of factors, including the underlying etiology, presence of chronic illness, host immune response, and timing of recognition and therapy.

Chapter 71

Respiratory Distress and Failure

Ashok P. Sarnaik, Jeff A. Clark, and Ajit A. Sarnaik

The term **respiratory distress** is often used to indicate signs and symptoms of abnormal respiratory pattern. A child with nasal flaring, tachypnea, chest wall retractions, stridor, grunting, dyspnea, and wheezing is often judged as having respiratory distress. The magnitude of these findings is used to judge the clinical severity of respiratory distress. Although nasal flaring is a nonspecific sign, the other signs are useful in localizing the site of pathology (see Chapters 373 and 374). Respiratory failure is defined as inability of the lungs to provide sufficient oxygen (hypoxic respiratory failure) or remove carbon dioxide (ventilatory failure) to meet metabolic demands. Whereas respiratory

Table 71-1 Typical Localizing Signs for Pulmonary Pathology

SITE OF PATHOLOGY	RESPIRATORY RATE	RETRACTIONS	AUDIBLE SOUNDS
Extrathoracic airway	↑	↑↑↑↑	Stridor
Intrathoracic extrapulmonary	↑	↑↑	Wheezing
Intrathoracic intrapulmonary	↑↑	↑↑	Wheezing
Alveolar interstitial	↑↑↑	↑↑↑	Grunting

distress is a clinical impression, the diagnosis of **respiratory failure** indicates inadequacy of oxygenation or ventilation, or both. Respiratory distress can occur in patients without respiratory disease, and respiratory failure can occur in patients without respiratory distress.

RESPIRATORY DISTRESS

A careful physical examination must be performed when managing a child in respiratory distress. Nasal flaring is an extremely important sign of distress, especially in infants. It is indicative of discomfort, pain, fatigue, or breathing difficulty. The state of responsiveness is another crucial sign. Lethargy, disinterest in surroundings, and poor cry are suggestive of exhaustion, hypercarbia, and impending respiratory failure. Abnormalities of the rate and depth of respirations can occur with both pulmonary and nonpulmonary causes of respiratory distress. In diseases of decreased lung compliance, such as pneumonia and pulmonary edema, respirations are characteristically rapid and shallow (decreased tidal volume). In obstructive airway diseases, such as asthma and laryngotracheitis, respirations are deep (increased tidal volume) but less rapid. Rapid and deep respirations without other respiratory signs should alert the physician to the possibility of nonrespiratory causes of respiratory distress, such as response to metabolic acidosis (diabetic ketoacidosis, renal tubular acidosis) or stimulation of the respiratory center (encephalitis, ingestion of central nervous system [CNS] stimulants). Chest wall, suprasternal, and subcostal retractions are manifestations of increased inspiratory effort, weak chest wall, or both. Inspiratory stridor indicates airway obstruction above the thoracic inlet, whereas expiratory wheezing results from airway obstruction below the thoracic inlet. Grunting is most commonly heard in diseases with decreased functional residual capacity (e.g., pneumonia, pulmonary edema) and peripheral airway obstruction (e.g., bronchiolitis).

Respiratory Disease Manifesting as Respiratory Distress

Clinical examination is important in localizing the site of pathology (see Chapter 373). Extrathoracic airway obstruction occurs anywhere above the thoracic inlet. Inspiratory stridor, suprasternal, chest wall, and subcostal retractions, and prolongation of inspiration are hallmarks of extrathoracic airway obstruction. By comparison, features of intrathoracic airway obstruction are prolongation of expiration and expiratory wheezing. Typical manifestations of alveolar interstitial pathology are rapid, shallow respirations, chest wall retractions, and grunting. The site of pathology can be localized and the differential diagnosis established on the basis of the clinical signs and symptoms (Tables 71-1 and 71-2).

Respiratory Distress without Respiratory Disease

Although respiratory distress most commonly results from diseases of lungs, airways, and chest wall, pathology in other organ systems can manifest as "respiratory distress" and lead to misdiagnosis and inappropriate management (Table 71-3). Respiratory distress resulting from heart failure or diabetic ketoacidosis may be misdiagnosed as asthma and improperly treated with albuterol, resulting in worsened hemodynamic state or ketoacidosis. Careful history and physical examination provide essential clues in avoiding misdiagnosis.

Table 71-2 Examples of Anatomic Sites of Lesions Causing Respiratory Failure

Cardiovascular Disease Manifesting as Respiratory Distress

A child with cardiovascular pathology may present with respiratory distress caused by 2 mechanisms: (1) decreased lung compliance and (2) cardiogenic shock (Table 71-4). Diseases that result in an increased pulmonary arterial blood flow (e.g., left-to-right shunts) or increased pulmonary venous pressure (e.g., left ventricular dysfunction from hypertension or myocarditis, obstructed total anomalous pulmonary

Table 71-3 Nonpulmonary Causes of Respiratory Distress

	EXAMPLE(S)	MECHANISM(S)
Cardiovascular	Left-to-right shunt Congestive heart failure Cardiogenic shock	↑ Pulmonary blood/water content Metabolic acidosis Baroreceptor stimulation
Central nervous system	Increased intracranial pressure Encephalitis Neurogenic pulmonary edema Toxic encephalopathy	Stimulation of brainstem respiratory centers
Metabolic	Diabetic ketoacidosis Organic acidemia Hyperammonemia	Stimulation of central and peripheral chemoreceptors
Renal	Renal tubular acidosis Hypertension	Stimulation of central and peripheral chemoreceptors Left ventricular dysfunction → increased pulmonary blood/water content
Sepsis	Toxic shock syndrome Meningococcemia	Cytokine stimulation of respiratory centers Baroreceptor stimulation from shock Metabolic acidosis

venous return) cause an increase in pulmonary capillary pressure and transudation of fluid into the pulmonary interstitium and alveoli. The increased pulmonary blood and water content leads to decreased lung compliance and results in rapid shallow respirations.

It is important to recognize that interstitial lung edema can not only manifest as alveolar fluid, but as small airway obstruction as well. Wheezing as a sign of congestive cardiac disease is common in infants and young children and should be recognized. Patients with cardiac lesions that result in a low cardiac output state, such as obstructive lesions of left side of the heart and acquired or congenital cardiomyopathy, often present in a state of shock with decreased tissue perfusion and metabolic acidosis. Such children demonstrate respiratory distress because of stimulation of chemoreceptors by metabolic acidosis and stimulation of baroreceptors by decreased blood pressure. The likelihood of a particular cardiovascular illness manifesting as respiratory distress depends on age at presentation (Table 71-5).

Neurologic Disease Manifesting as Respiratory Distress

CNS dysfunction can lead to alterations in respiratory patterns. Increased intracranial pressure (ICP) may manifest as respiratory distress. Early rise in ICP results in stimulation of respiratory centers, leading to increases in the rate (tachypnea) and depth (hyperpnea) of respiration. The resultant decrease in Pa_{CO_2} and elevation of cerebrospinal fluid pH lead to cerebral vasoconstriction and amelioration of intracranial hypertension. Cerebral hemispheric and midbrain lesions often result in hyperpnea as well as tachypnea. In such situations, blood gas measurements typically show respiratory alkalosis without hypoxemia. Pathology affecting the pons and medulla manifests as irregular breathing patterns such as apneustic breathing (prolonged inspiration with brief expiratory periods), Cheyne-Stokes breathing (alternate periods of rapid and slow breathing), and irregular, ineffective breathing or apnea. Level of consciousness is most often impaired when abnormal breathing pattern from a brainstem disorder is present. Along with respiratory changes, other manifestations of CNS dysfunction and increased ICP may be present, such as focal neurologic signs, pupillary changes, hypertension, and bradycardia (see Chapter 63). Occasionally, severe CNS dysfunction can result in **neurogenic pulmonary edema** and respiratory distress, which may be a result of excessive sympathetic discharge resulting in increased pulmonary venous hydrostatic pressure as well as increased pulmonary capillary

Table 71-5 Typical Chronology of Heart Disease Presentation in Children

AGE	MECHANISM	DISEASE
Newborn (1-10 days)	↑ Arteriovenous pressure difference	Arteriovenous fistula (brain, liver)
	Ductal closure	Single ventricle lesions or severe ventricular outflow obstruction
	Independent pulmonary and systemic blood flow	Transposition of the great arteries
	Pulmonary venous obstruction	Total anomalous pulmonary venous return (TAPVR)
Young Infant (1-6 mo)	↓ Pulmonary vascular resistance	Left-to-right shunt
	↓ Pulmonary artery pressure	Anomalous left coronary artery to the pulmonary artery
Any Age	Rate disturbance	Tachy- or bradyarrhythmias
	Infection	Myocarditis, pericarditis
	Abnormal cardiac myocytes	Cardiomyopathy
	Excess afterload	hypertension

permeability. **Central neurogenic hyperventilation** is characteristically observed in CNS involvement by illnesses such as urea cycle defects and encephalitis. **Bradycardia and apnea** may be caused by CNS-depressant medications, poisoning, prolonged hypoxia, trauma, or infection (see Table 71-2).

Toxic-Metabolic States Manifesting as Respiratory Distress

Direct stimulation of respiratory centers resulting in respiratory alkalosis is encountered in certain intoxications, such as those involving salicylates and theophylline. Similarly, intoxication with general CNS stimulants, such as cocaine and amphetamines may manifest as increased respirations. Presence of endogenous and exogenous toxins, such as organic acidemias, ingestion of methanol and ethylene glycol, and late stages of salicylism, cause metabolic acidosis and compensatory hyperventilation, which can manifest as respiratory distress. Blood gas measurements show decreased pH and compensatory hypocarbia with normal oxygenation. Metabolic disorders causing hyperammonemia, on the other hand, cause respiratory alkalosis (decreased $Paco_2$ with increased pH) because ammonia is a stimulant of respiratory centers.

Other Nonpulmonary Entities Manifesting as Respiratory Distress

Sepsis and septic shock may manifest as respiratory distress by causing acute respiratory distress syndrome (ARDS), hypovolemic stimulation of baroreceptors, stimulation of respiratory centers by cytokines, and lactic acidosis. Other indirect causes of lung injury include systemic inflammatory conditions, trauma, transfusion-related acute lung injury, and pancreatitis. Similarly, renal disease may manifest as respiratory distress by causing metabolic acidosis (e.g., renal tubular acidosis or renal failure) or hypertensive left ventricular failure and fluid overload.

RESPIRATORY FAILURE

Respiratory failure occurs when oxygenation and ventilation are insufficient to meet the metabolic demands of the body. Respiratory failure may result from an abnormality in (1) lung and airways, (2) chest wall and muscles of respiration, or (3) central and peripheral chemoreceptors. Clinical manifestations depend largely on the site of pathology (Table 71-6). Although respiratory failure is traditionally defined as respiratory dysfunction resulting in Pao_2 <60 torr with breathing of room air and $Paco_2$ >50 torr resulting in acidosis, the patient's general state, respiratory effort, and potential for impending exhaustion are more important indicators than blood gas values.

Acute lung injury due to pneumonia, sepsis, aspiration, drowning, embolism, trauma, smoke inhalation, or drug overdose may lead to the **ARDS** (Tables 71-7 and 71-8; Fig. 71-1).

Pathophysiology of Respiratory Failure

Respiratory failure can be classified into (1) hypoxic respiratory failure (failure of oxygenation) and (2) hypercarbic respiratory failure (failure of ventilation). Systemic venous (pulmonary arterial) blood is arterialized after equilibration with alveolar gas in the pulmonary capillaries and is carried back to the heart by pulmonary veins. The arterial gas is influenced by the composition of inspired gas, and the effectiveness of alveolar ventilation, pulmonary capillary perfusion, and diffusion capacity of the alveolar capillary membrane. Abnormality at any of these steps can result in respiratory failure. Hypoxic respiratory failure results from intrapulmonary shunting and venous admixture or insufficient diffusion of oxygen from alveoli into pulmonary capillaries. This can be

Table 71-6 Typical Clinical Manifestations of Respiratory Failure

SITE OF PATHOLOGY	SYMPTOM
Lung and Airways	Nasal flaring, retractions, tachypnea, wheezing stridor, grunting
Chest wall and muscles of respiration	Nasal flaring, tachypnea, paradoxical respirations
Respiratory control	Shallow or slow respirations, abnormal respiratory patterns, apnea

Table 71-7 Simplified Consensus Definition of Acute Lung Injury

- Acute onset (<7 days)
- Severe hypoxemia (PaO_2/FIO_2 <300 for acute lung injury, or <200 for acute respiratory distress syndrome)
- Diffuse bilateral pulmonary infiltrates on frontal radiograph consistent with pulmonary edema (these can be patchy and asymmetric, and pleural effusions can be present)
- Absence of left atrial hypertension (pulmonary artery wedge pressure <18 mm Hg if measured)

Table 71-8 New Berlin Definition of ARDS in Infancy and Early Childhood

	BERLIN DEFINITION CRITERIA	SUITABILITY IN INFANTS
Timing	Within 1 wk of a known clinical insult or new or worsening respiratory symptoms	Acute time frame is specified
Chest X-rays or tomography scan	Bilateral opacities not fully explained by effusions, lobar/lung collapse, or nodules. (Illustrative clinical cases and chest X-rays have been provided)	Including illustrative radiographs is important, because ARDS appearance may be different in children and in adults
Origin of edema	Respiratory failure not fully explained by cardiac failure or fluid overload. Need objective assessment (e.g., echocardiography) to exclude hydrostatic edema, if no ARDS risk factors are present	Echocardiography widely used, whereas Swan-Ganz catheters are rarely used in early childhood. Including risk factors in the ARDS definition is important, because they may be different in children and in adults
Oxygenation*		
Mild	200 mm Hg < PaO_2/FIO_2 ≤ 300 mm Hg with PEEP or CPAP ≥ 5 cm H_2O†	Noninvasive CPAP is widely used in early childhood. PEEP threshold (5 cm H_2O) is a value commonly used during early childhood
Moderate	100 mm Hg < PaO_2/FIO_2 ≤ 200 mm Hg with PEEP ≥ 5 cm H_2O	
Severe	PaO_2/FIO_2 < 100 mm Hg with PEEP ≥ 5 cm H_2O	

*If altitude is higher than 1,000 m, the correction factor should be calculated as follows: [PaO_2/FIO_2 × (barometric pressure/760)].
†This may be delivered noninvasively in the mild acute respiratory distress syndrome group.
CPAP, continuous positive airway pressure; FIO_2, fraction of inspired oxygen; PaO_2, partial pressure of arterial oxygen; PEEP, positive end-expiratory pressure.

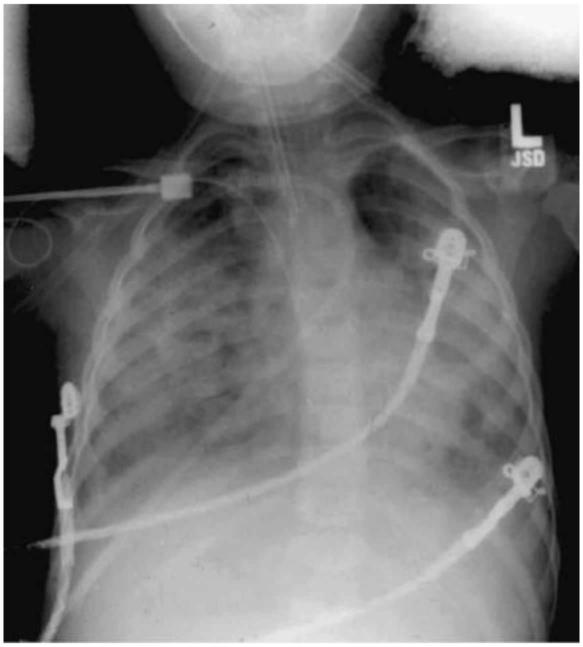

Figure 71-1 Frontal portal chest radiograph showing diffuse bilateral infiltrates consistent with acute lung injury. *(From Wheeler AP, Bernard GR: Acute lung injury and the acute respiratory distress syndrome: a clinical review*, Lancet *369:1553–1564, 2007.)*

caused by conditions such as small airway obstruction, increased barrier to diffusion (such as interstitial edema or fibrosis), or in conditions where alveoli are collapsed or filled with fluid (e.g., ARDS, pneumonia, atelectasis, or pulmonary edema). In most cases, hypoxic respiratory failure is associated with a decreased functional residual capacity, and can be managed by recruitment with positive pressure ventilation. Hypercarbic respiratory failure is caused by decreased minute alveolar ventilation (tidal volume multiplied by respiratory rate). This can occur from centrally-mediated disorders of respiratory drive, increased dead space ventilation, or obstructive airway disease. The two entities may coexist as a combined failure of oxygenation and ventilation.

Ventilation–Perfusion Mismatch, Venous Admixture, Intrapulmonary Shunt

For exchange of O_2 and CO_2 to occur, alveolar gas must be exposed to blood in pulmonary capillaries. Both ventilation and perfusion are lower in nondependent areas of the lung and higher in dependent areas of the lung. The difference in perfusion ($\dot{Q}$) is greater than the difference in ventilation ($\dot{V}$). Perfusion in excess of ventilation results in incomplete "arterialization" of systemic venous (pulmonary arterial) blood and is referred to as *venous admixture*. Perfusion of unventilated areas is referred to as *intrapulmonary shunting* of systemic venous blood to systemic arterial circulation. Conversely, ventilation that is in excess of perfusion is "wasted"; that is, it does not contribute to gas exchange and is referred to as *dead space ventilation*. Dead space ventilation results in return of greater amounts of atmospheric gas which has not participated in gas exchange and has negligible CO_2 to the atmosphere during exhalation. The end result is a decrease in mixed expired P_{CO_2} (P_{ECO_2}) and an increase in the Pa_{CO_2}-P_{ECO_2} gradient. The fraction of tidal volume that occupies dead space (V_D/V_T) is calculated as follows:

$$[(Pa_{CO_2} - P_{ECO_2}) \div Pa_{CO_2}]$$

Normal V_D/V_T is around 0.33. V_D/V_T increases in states that result in decreased pulmonary perfusion, such as pulmonary hypertension, hypovolemia, and decreased cardiac output. Venous admixture and intrapulmonary shunting predominantly affect oxygenation, resulting in a P_{AO_2}-Pa_{O_2} (A-aO_2) gradient without elevation in Pa_{CO_2}. This is caused by the greater ventilation of perfused areas, which is sufficient to normalize Pa_{CO_2} but not Pa_{O_2} because of their respective dissociation curves (see Chapter 365). The relative straight-line relationship of hemoglobin-CO_2 dissociation allows for averaging of P_{CO_2} from hyperventilated and hypoventilated areas. Because the association between oxygen tension and hemoglobin saturation plateaus with increasing Pa_{O_2}, the decreased hemoglobin-O_2 saturation in poorly ventilated areas cannot be compensated for by well-ventilated areas where hemoglobin-O_2 saturation has already reached near-maximum. This results in decreased arterial oxyhemoglobin saturation (Sa_{O_2}) and Pa_{O_2}. Elevation of Pa_{CO_2} in such situations is indicative of coincident alveolar hypoventilation. Examples of diseases leading to venous admixture include asthma and aspiration pneumonia, and those of intrapulmonary shunt include lobar pneumonia and ARDS.

Diffusion

Even if ventilation and perfusion are matched, gas exchange requires diffusion across the interstitial space between alveoli and pulmonary capillaries. Under normal conditions, there is sufficient time for the pulmonary capillary blood to equilibrate with alveolar gas across the interstitial space. When the interstitial space is filled with inflammatory cells or fluid, diffusion is impaired. Because the diffusion capacity of CO_2 is 20 times greater than that of O_2, diffusion defects manifest as hypoxemia rather than hypercarbia. Even with the administration of 100% oxygen, P_{AO_2} increases to around 660 torr from 100 torr at sea level, and the concentration gradient for diffusion of O_2 is increased by only 6.6 times. Therefore, with diffusion defects, lethal hypoxemia will set in before clinically significant CO_2 retention results. In fact, in such situations P_{CO_2} is often decreased because of the hyperventilation that accompanies hypoxemia. Presence of hypercarbia in diseases that impair diffusion is indicative of alveolar hypoventilation from coexisting airway obstruction, exhaustion, or CNS depression. Examples of disease that impair diffusion are interstitial pneumonia, ARDS, scleroderma, and pulmonary lymphangiectasia.

MONITORING A CHILD IN RESPIRATORY DISTRESS AND RESPIRATORY FAILURE

Clinical Examination

It cannot be overemphasized that clinical observation is the most important component of monitoring. The presence and magnitude of abnormal clinical findings, their progression with time, and their temporal relation to therapeutic interventions serve as guides to diagnosis and management (see Chapter 373). As much as possible, the child with respiratory distress or failure should be observed in the position of greatest comfort and in the least threatening environment.

Pulse oximetry is the most commonly utilized technique to monitor oxygenation. Noninvasive and safe, it is the standard of care in bedside monitoring of children during transport, procedural sedation, surgery, and critical illness. It indirectly measures arterial hemoglobin-O_2 saturation by differentiating oxyhemoglobin from deoxygenated hemoglobin using their respective light absorption at wavelengths of 660 nm (red) and 940 nm (infrared). A pulsatile circulation is required to enable detection of oxygenated blood entering the capillary bed. Percentage of oxyhemoglobin is reported as Sa_{O_2}; however, the correct description is oxyhemoglobin saturation as measured by pulse oximetry (Sp_{O_2}). This is because Sp_{O_2} may not reflect Sa_{O_2} in certain situations. It is important to be familiar with the hemoglobin-O_2 dissociation curve (see Chapter 373) in order to estimate Pa_{O_2} at a given oxyhemoglobin saturation. Because of the shape of the hemoglobin-O_2 dissociation curve, changes in Pa_{O_2} above 70 torr are not readily identified by pulse oximetry. Also, at the same Pa_{O_2} level, there may be a significant change in Sp_{O_2} at a different blood pH value. In most situations, an Sp_{O_2} value greater than 95% is a reasonable goal, especially in emergency situations. There are exceptions, such as in patients with single ventricle cardiac lesions, in whom the pulmonary and systemic circulations are receiving blood flow from the same ventricle (e.g., after Norwood procedure for hypoplastic left heart syndrome), or with large left-to-right shunts (e.g., ventricular septal defect and patent ductus arteriosus). In these types of pathophysiologic situations, a lower Sp_{O_2}

is desired to avoid excessive blood flow to the lungs and pulmonary edema from the pulmonary vasodilatory effects of oxygen, and, in the patient with a single ventricle, diverting blood flow away from the systemic circulation. Because most commercially available pulse oximeters recognize all types of hemoglobin as either oxyhemoglobin or deoxygenated hemoglobin, they provide inaccurate information in the presence of carboxyhemoglobin and methemoglobin. In carbon monoxide poisoning, carboxyhemoglobin absorbs light in the same (red) wavelength as oxyhemoglobin, leading to overestimation of oxygen saturation. Methemoglobin absorbs light in both the oxygenated and deoxygenated wavelengths, which can cause either an overestimation or underestimation of oxygen saturation. Data suggests that increasing methemoglobin concentrations tend to drive Spo_2 toward 85%, no matter the actual percent of oxyhemoglobin. At lower methemoglobin levels, the pulse oximetry reading is falsely low, whereas high levels lead to a falsely high pulse oximetry reading. Newer pulse oximeters may have the ability to distinguish dyshemoglobinemias and to prevent false readings, but these are not currently in widespread use. It should be recognized that dangerous levels of hypercarbia may exist in patients with ventilatory failure, who have satisfactory Spo_2 if they are receiving supplemental oxygen. Pulse oximetry should not be the only monitoring method in patients with primary ventilatory failure, such as neuromuscular weakness and CNS depression. It is also unreliable in patients with poor perfusion and poor pulsatile flow to the extremities. Despite these limitations, pulse oximetry is a noninvasive, easily applicable, and effective means of evaluating the percentage of oxyhemoglobin in most patients.

Capnography (end-tidal CO_2 measurement) is helpful in determining the effectiveness of ventilation and pulmonary circulation. This method is especially useful for monitoring the level of ventilation in intubated patients. Diseases resulting in increased dead space or decreased pulmonary blood flow lead to decreases in end-tidal CO_2 and an overestimation of the adequacy of ventilation.

Blood Gas Abnormalities in Respiratory Distress and Respiratory Failure

Arterial blood gas analysis offers valuable assistance in diagnosis, monitoring, and management of a child in respiratory distress and failure. Because of technical difficulties in obtaining an arterial sample in children, a capillary blood gas (CBG) sample is most often obtained in emergency situations. A properly “arterialized” CBG sample obtained by warming the digit and obtaining free flowing blood is acceptable. The blood sample needs to be processed without delay. CBG provides a good estimate of $Paco_2$ and arterial pH, but less so for Pao_2. In patients who mainly require monitoring of their ventilation (especially those whose oxygenation is being monitored with pulse oximetry) a venous blood gas sample provides reliable estimate of arterial pH and Pco_2 values, provided tissue perfusion is reasonably adequate. Venous Pco_2 is approximately 6 torr higher and pH approximately 0.03 lower than the arterial values. Venous Po_2 has a poor correlation with Pao_2. Mixed venous O_2 saturation obtained from a central venous catheter in the right atrium is an excellent marker of the balance between oxygen delivery and oxygen consumption. In patients with a constant arterial O_2 content and O_2 consumption, mixed venous O_2 saturation offers valuable information regarding cardiac output.

Blood gas analysis is important not only for determining the adequacy of oxygenation and ventilation but also for determining site of the respiratory pathology and planning treatment (see Chapter 373). Briefly, in presence of pure alveolar hypoventilation (such as airway obstruction above the carina, decreased CO_2 responsiveness and neuromuscular weakness), the blood gas will show respiratory acidosis with an elevated Pco_2 but a relative sparing of oxygenation. $\dot{V}/\dot{Q}$ mismatch (peripheral airway obstruction, bronchopneumonia) will be reflected in increasing hypoxemia and variable levels of Pco_2 (low, normal, high) depending on severity of disease. Intrapulmonary right to left shunting and diffusion defects (alveolar-interstitial diseases such as pulmonary edema, ARDS) will be associated with a large A-ao_2 gradient and hypoxemia with relative sparing of CO_2 elimination unless there is coincident fatigue or CNS depression.

Acid–Base Abnormalities in a Child with Respiratory Distress and Respiratory Failure

It is crucial to analyze the magnitude and appropriateness of changes in pH, Pco_2 and bicarbonate (HCO_3^-) as they provide useful clues to the underlying pathophysiology and presence of more than one disorder. To do so, it is useful to assume baseline values of pH 7.40, Pco_2 40 torr, and HCO_3^- 24 mEq/L. Newborns have lower renal threshold for bicarbonate and therefore have slightly different baseline values of pH 7.38, Pco_2 35 torr and HCO_3^- 20 mEq/L.

Metabolic Acidosis with Respiratory Compensation

Patients with metabolic acidosis have decreased pH resulting from decreased serum bicarbonate. Chemoreceptor stimulation results in hyperventilation and respiratory compensation which may clinically manifest as respiratory distress. It should be recognized that a normal compensation does not completely correct the pH but rather minimizes a change in pH that would otherwise occur without compensation. The adequacy of respiratory compensation is judged by the extent of the decline in $Paco_2$ in response to the decline in HCO_3^- or pH. A normal compensation for metabolic acidosis results in a fall in Pco_2 by 1.2 torr for every 1 mEq/L fall in HCO_3^- The most commonly used method to analyze the adequacy of respiratory compensation is the Winter’s formula: $Paco_2 = (HCO_3^- \times 1.5) + 8 \pm 2$. A quick method is to look at the last 2 digits of pH (provided it is not below 7.10) which should be within 2 torr of Pco_2. For example, pH 7.27, Pco_2 26 torr, and bicarbonate 12 mEq/L represents metabolic acidosis with a normal respiratory compensation response. On the other hand, pH 7.15, Pco_2 30 torr, and HCO_3^- 10 mEq/L constitutes metabolic acidosis with inadequate respiratory compensation. The reasons for inadequate compensation include decreased CO_2 responsiveness (e.g. narcotic poisoning, cerebral edema), abnormalities of lungs and airways, or neuromuscular weakness. A decrease in $Paco_2$ that is greater than what could be expected as a normal compensatory response to metabolic acidosis is indicative of a mixed disorder. For example, a pH 7.20, Pco_2 15 torr, and HCO_3^- 7.5 mEq/L represents metabolic acidosis with a concomitant respiratory alkalosis because the decline in Pco_2 is greater than what can be expected as normal compensation. Combination of metabolic acidosis and respiratory alkalosis is often encountered in serious conditions such as cardiogenic shock (anxiety, stimulation of baroreceptors), sepsis, or toxic-metabolic states (salicylates, organic academia).

Respiratory Acidosis with Metabolic Compensation

Patients with respiratory acidosis have decreased pH as a result of elevated $Paco_2$. An acute increase in Pco_2 of 10 torr results in a decrease in pH by 0.08. Thus, a child with severe status asthmaticus and a $Paco_2$ of 60 torr will have blood pH of around 7.24. Chronically elevated (greater than 3-5 days) $Paco_2$ is accompanied by renal compensation and increase in serum bicarbonate limiting the fall in pH to 0.03 for every 10 torr rise in $Paco_2$. Thus an infant with bronchopulmonary dysplasia who has a basal $Paco_2$ of 60 torr will have blood pH around 7.34. These findings are helpful in distinguishing acute vs. chronic changes in $Paco_2$. Also, for a given level of CO_2 accumulation, a decrease in pH that is greater than expected is indicative of concomitant metabolic acidosis and a decline in pH that is less than expected is due to accompanying metabolic alkalosis.

Assessment of Oxygenation and Ventilation Deficits

For standardizing management, following clinical progress, and determining prognosis for patients with defects in oxygenation or ventilation, various indicators have been proposed. Each one has its strengths and limitations:

A-ao_2 gradient: Calculated by subtracting arterial Po_2 from alveolar Po_2 ($PAo_2 - Pao_2$). For the comparison to be valid, it must be at the same Fio_2.

Pao_2/Fio_2 ratio is calculated by dividing arterial Po_2 by Fio_2. In hypoxic respiratory failure, a Pao_2/Fio_2 value <300 is consistent with acute lung injury, and a value <200 is consistent with ARDS.

Although the intent is to measure $\dot{V}/\dot{Q}$ mismatch, intrapulmonary shunt, and diffusion defect, the status of alveolar hypoventilation could have a significant impact on PaO_2/FIO_2.

PaO_2/PAO_2 is determined by dividing arterial PO_2 by alveolar PO_2. The level of alveolar ventilation is accounted for in the calculation of PAO_2. Therefore, PaO_2/PAO_2 is more indicative of $\dot{V}/\dot{Q}$ mismatch and alveolar capillary integrity.

Oxygenation index (OI) is aimed at standardizing oxygenation to the level of therapeutic interventions such as mean airway pressure (MAP) and FIO_2, which are directed toward improving oxygenation. None of the previously mentioned indicators of oxygenation account for the degree of positive pressure respiratory support. OI is calculated as follows:

$$OI = \left(MAP \times \%\, O_2\ inspired\right) \div PaO_2$$

The limitation of OI is that level of ventilation is not accounted for in the assessment.

Ventilation index (VI) is aimed at standardizing alveolar ventilation to the level of therapeutic interventions (such as peak inspiratory pressure [PIP] and ventilator rate) directed toward lowering $PaCO_2$. VI is calculated as follows:

$$VI = \left[Ventilator\ Rate \times (PIP - PEEP) \times PaCO_2\right] \div 1000$$

MANAGEMENT

The goal of management for respiratory distress and respiratory failure is to ensure a patent airway and provide necessary support for adequate oxygenation of the blood and removal of CO_2. Compared with hypercapnia, hypoxemia is a life-threatening condition; therefore, initial therapy for respiratory failure should be aimed at ensuring adequate oxygenation.

Oxygen Administration

Supplemental oxygen administration is the least invasive and most easily tolerated therapy for hypoxemic respiratory failure. *Nasal cannula* oxygen provides low levels of oxygen supplementation and is easy to administer. Oxygen is humidified in a bubble humidifier and delivered via nasal prongs inserted in to the nares. In children, a flow rate <5 L/min is most often used because of increasing nasal irritation with higher rates. A common formula for an estimation of the FIO_2 during use of a nasal cannula in older children and adults is as follows:

$$FIO_2\%\, O_2\ \text{delivered} = 21\% + \left[\left(\text{nasal cannula flow (L/min)} \times 3\right)\right]$$

The typical FIO_2 value using this method is between 23% and 40%, although the FIO_2 varies according to the size of the child, the respiratory rate, and the volume of air moved with each breath. In a young child, because typical nasal cannula flows are a greater percentage of total minute ventilation, significantly higher FIO_2 may be provided. Alternately, a *simple mask* may be employed, which consists of a mask with open side ports and a valveless oxygen source. Variable amounts of room air are entrained through the ports and around the side of the mask, depending on the fit, size, and minute volume of the child. Oxygen flow rates vary from 5-10 L/min, yielding typical FIO_2 values between 0.30 and 0.65. If more precise delivery of oxygen is desired, other mask devices should be used.

A *Venturi mask* delivers preset fractions of oxygen through a mask and reservoir system by entraining precise amounts of room air into the reservoir with high-flow oxygen. The amount of room air entrainment and subsequent FIO_2 are determined by the adapter at the end of each mask reservoir. The adapter can be chosen to provide between 30% and 50% oxygen concentrations. Oxygen flow rates of 5-10 L/min are recommended to achieve desired FIO_2 and to prevent rebreathing. *Partial rebreather* and *nonrebreather* masks use a reservoir bag attached to a mask to provide higher fractions of oxygen. Partial rebreather masks have 2 open exhalation ports and contain a valveless oxygen reservoir bag. Some exhaled gas can mix with reservoir gas during exhalation, although most exits the mask via the exhalation ports. Through these ports, room air is also entrained during inspiration. A partial rebreather mask can provide up to 0.6 FIO_2 as long as oxygen flow is adequate to keep the bag from collapsing (typically 10-15 L/min). As with nasal cannulas, smaller children with smaller tidal volumes entrain less room air, and their FIO_2 values will be higher. Nonrebreather masks include 2 one-way valves, 1 between the oxygen reservoir bag and the mask and 1 on 1 of the 2 exhalation ports. This arrangement minimizes mixing of exhaled and fresh gas and entrainment of room air during inspiration. The second exhalation port has no valve, a safeguard to allow some room air to enter the mask in the event of disconnection from the oxygen source. A nonrebreather mask can provide up to 0.95 FIO_2. The use of a nonrebreather mask in conjunction with an oxygen blender allows delivery of fractions of oxygen between 0.50 and 0.95. When supplemental oxygen alone is inadequate to improve oxygenation, or when ventilation problems coexist, additional therapies may be necessary.

Airway Adjuncts

Maintenance of a patent airway is a critical step in maintaining adequate oxygenation and ventilation. Artificial pharyngeal airways may be useful in patients with oropharyngeal or nasopharyngeal airway obstruction and in those with neuromuscular weakness in whom native extrathoracic airway resistance contributes to respiratory compromise. An *oropharyngeal airway* is a stiff plastic spacer with grooves along each side that can be placed in the mouth to run from the teeth along the tongue to its base just above the vallecula. The spacer prevents the tongue from opposing the posterior pharynx and occluding the airway. Because the tip sits at the base of the tongue, it is usually not tolerated by patients who are awake or whose gag reflex is strong. The *nasopharyngeal airway*, or nasal trumpet, is a flexible tube that can be inserted into the nose to run from the nasal opening along the top of the hard and soft palate with the tip ending in the hypopharynx. It is useful in bypassing obstruction from enlarged adenoids or from contact of the soft palate with the posterior nasopharynx. Because it is inserted past the adenoids, a nasopharyngeal airway should be used with caution in patients with bleeding tendencies.

Inhaled Gases

Helium-oxygen mixture (*heliox*) is useful in overcoming airway obstruction and improving ventilation. Helium is much less dense and slightly more viscous than nitrogen. When substituted for nitrogen, helium helps maintain laminar flow across an obstructed airway, decreases airway resistance, and improves ventilation. It is especially helpful in diseases of large airway obstruction in which turbulent airflow is more common, such as acute laryngotracheobronchitis, subglottic stenosis, and vascular ring. It is also used in patients with severe status asthmaticus. To be effective, helium should be administered in concentrations of at least 60%, so associated hypoxemia may limit its use in patients requiring more than 40% oxygen. *Nitric oxide (NO)* is a powerful inhaled pulmonary vasodilator. Its use may improve pulmonary blood flow and $\dot{V}/\dot{Q}$ mismatch in patients with diseases that elevate pulmonary vascular resistance, such as persistent pulmonary hypertension of the newborn, primary pulmonary hypertension, and secondary pulmonary hypertension as a result of chronic excess pulmonary blood flow (e.g., ventriculoseptal defect) or collagen vascular diseases. NO is administered in doses ranging from 5-20 parts per million. Although administration of NO to unintubated patients is possible, it is usually administered to patients receiving mechanical ventilation through endotracheal tubes, because of the need for precision in NO dosing.

Positive-Pressure Respiratory Support

Noninvasive positive-pressure respiratory support is useful in treating both hypoxemic and hypoventilatory respiratory failure. Positive airway pressure helps aerate partially atelectatic or filled alveoli, prevent alveolar collapse at end exhalation, and increase functional residual capacity (FRC). This improves pulmonary compliance and hypoxemia and decreases intrapulmonary shunt. In addition, positive pressure ventilation is useful in preventing collapse of extrathoracic airways by maintaining positive airway pressure during inspiration. Improving compliance and overcoming airway resistance also improves tidal volume and, therefore, ventilation. A **high-flow nasal cannula** delivers

gas flow at 4-16 L/min, providing significant continuous positive airway pressure (CPAP). The amount of CPAP provided is not quantifiable and varies with each patient, depending on the percentage of total inspiratory flow that is delivered from the cannula, airway anatomy, and degree of mouth breathing. In small children, the relative amount of CPAP for a given flow is usually greater than in older children, and may provide significant positive pressure. The F_{IO_2} can be adjusted by provision of gas flow through an oxygen blender. Another benefit of a high-flow nasal cannula system is the washout of CO_2 from the nasopharynx, which decreases rebreathing of CO_2 and dead space ventilation. For delivery of high-flow air or oxygen, adequate humidification is essential and is achieved with use of a separate heated humidification chamber. CPAP can also be provided through snugly fitting nasal prongs or a tight-fitting facial mask attached to a ventilator or other positive-pressure device. Noninvasive CPAP is most useful in diseases of mildly decreased lung compliance and low FRC, such as atelectasis and pneumonia. Diseases of extrathoracic airway obstruction in which extrathoracic negative airway pressures during inspiration lead to airway narrowing (e.g., laryngotracheitis, obstructive sleep apnea, postextubation airway edema) may also benefit from CPAP. Potential risks include nasal irritation, hyperinflation from excessive CPAP in smaller patients, and abdominal distention from swallowed air.

Bilevel positive airway pressure (BiPAP) machines provide positive airway pressure during exhalation and additional positive pressure during inspiration. A BiPAP device allows one to set an expiratory positive airway pressure and an inspiratory positive airway pressure. The additional positive pressure during inspiration helps augment tidal volume and improve alveolar ventilation in low compliance and obstructive lung disease. The inspiratory and expiratory pressures can be adjusted independently to suit individual needs and comfort. Because of the additional support during inspiration, patients with neuromuscular weakness in particular tend to benefit from BiPAP support. BiPAP may also be helpful in diseases of intrathoracic airway obstruction. During exhalation, expiratory positive airway pressure can decrease the effects of airway closure by raising intraluminal pressure and ameliorating intrathoracic airway collapse. During inspiration, inspiratory positive airway pressure can unload inspiratory muscles, and decrease work of breathing (Fig. 71-2).

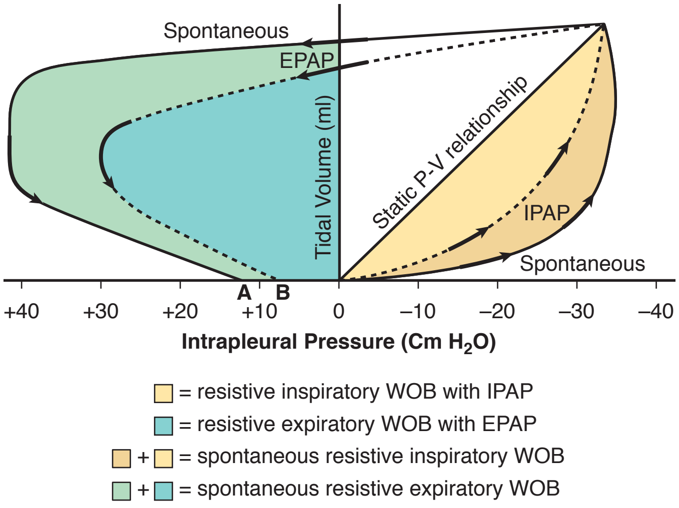

Figure 71-2 **Work of breathing (WOB) in status asthmaticus with and without noninvasive positive pressure ventilation.** In the expiratory limb of the respiratory cycle, the equal pressure point is displaced distally, causing airways to begin to close at a higher lung volume (increased closing capacity), leading to dynamic hyperinflation, and autopositive end-expiratory pressure (auto-PEEP) *(A)*. Application of expiratory positive airway pressure stents the airways, reducing intrathoracic airway collapse, dynamic hyperinflation, auto-PEEP *(B)*, and WOB. In the inspiratory limb, the patient needs to generate less negative pressure to initiate inspiration because of lower autopositive end-expiratory pressure. Inspiratory muscles are further unloaded by inspiratory positive airway pressure (IPAP) throughout inspiration for the given tidal volume. Both expiratory and inspiratory WOB are thus reduced by application of noninvasive positive pressure ventilation. *(From Sarnaik AA, Sarnaik AP: Noninvasive ventilation in pediatric status asthmaticus: Sound physiologic rationale but is it really safe, effective, and cost-efficient?* Pediatr Crit Care Med *13:484–485, 2012.)*

Endotracheal Intubation and Mechanical Ventilation

When hypoxemia or significant hypoventilation persists despite the interventions already described, tracheal intubation and mechanical ventilation are indicated. Additional indications for intubation include maintaining airway patency in patients who have the potential for airway compromise, such as those with actual or potential neurologic deterioration, and in patients with hemodynamic instability.

Proper monitoring is essential to ensuring a safe and successful tracheal intubation. Pulse oximetry, heart rate, and blood pressure monitoring are mandatory and should be forgone only in situations calling for emergency intubation. All necessary equipment, including bag-mask ventilation device, laryngoscope, tracheal tube with stylet, and suction equipment, must be available and working properly prior to initiation of intubation. The proper internal diameter (ID) for the tracheal tube can be estimated using the following formula:

$$ID = (Age\,[yr]/4) + 4$$

Table 71-9 provides average values for age, size, and depth of insertion for tracheal tubes. Preoxygenation of the patient with high fractions of inspired oxygen is essential and will allow maximum procedure time prior to the onset of hypoxemia.

Although intubation can be accomplished without sedation and pharmacologic paralysis in selected patients, the physiologic benefits of these measures to the patient as well as to the facilitation of the intubation usually far outweigh the risks; sedation and paralysis should be considered standard unless contraindicated. Administration of a sedative and analgesic followed by a paralytic agent is a common pharmacologic regimen for facilitating intubation. The particular type and dose of each agent often depends on the underlying disease and clinician preference. Table 71-10 lists commonly used agents. An alternative to this pharmacologic approach, especially when intubation is urgent or the patient is suspected of having a full stomach, increasing the risk of aspiration, is rapid sequence intubation (see Chapter 67).

Once adequate sedation and/or paralysis have been achieved, ventilation should be assisted with a bag-mask device. After optimal

Table 71-9 Average Size and Depth Dimensions for Tracheal Tubes

PATIENT AGE	INTERNAL DIAMETER (mm)	OROTRACHEAL DEPTH (cm)	NASOTRACHEAL DEPTH (cm)
Premature	2.0-3.0	8-9	9-10
Full-term neonate	3.0-3.5	10	11

preoxygenation, intubation can be performed. The clinician uses his/her dominant hand to open the patient's mouth and inserts the laryngoscope blade gently along the tongue to its base. The airway opening can be visualized by applying lift up and away from the clinician, along the axis of the laryngoscope handle. If a straight (Miller) laryngoscope blade is used, the epiglottis is lifted anteriorly by the tip of the blade to visualize the glottis. If a curved (Macintosh) blade is used, the tip should be advanced into the vallecula and then lifted to visualize the glottis. Secretions often obscure visualizations at this step and should be suctioned clear. Once clear visualization of the vocal cords is accomplished, the tube can be placed through the cords. Rapid confirmation of tube placement is essential and should be assessed by as many of the following steps as possible: Auscultation of both lung fields as well as the epigastrium for equal breath sounds and good air movement and evaluation of the abdomen for increasing distention should be performed. Adequate bilateral chest expansion and misting inside the tracheal tube with each breath are suggestive of proper tube placement. An increasing heart rate, if heart rate has decreased during the attempt, and a rising or normal pulse oximetry reading are suggestive of successful tube placement. Preoxygenation may significantly delay a drop in Spo_2 with improper tube placement, leading to a significant delay in its recognition. Confirmation of exhaled CO_2 is mandatory. It can be accomplished with use of a disposable colorimetric CO_2 detector or with capnography. In situations of very low pulmonary perfusion, such as cardiac arrest, exhaled CO_2 may not be detected. A chest radiograph should also be obtained to confirm proper placement of the tracheal tube, which should lie roughly halfway between the glottis and the carina (see Chapter 62).

Transient Manual Ventilation in the Immediate Preintubation and Postintubation Periods

Establishment of ventilation via bag and mask or bag and tracheal tube is required prior to transport of the patient to a setting of continued critical care. The technique of manual ventilation should take into account the underlying pathology. Ventilation of patients with diseases characterized by low FRC (pneumonia, pulmonary edema, ARDS, etc.) should include the application of positive end-expiratory pressure (PEEP) to prevent alveolar derecruitment. This can be accomplished with use of a PEEP valve on a self-inflating ventilation bag or by careful manipulation of exhaust gas using an anesthesia bag. Such diseases are also characterized by a short time constant and therefore are best managed with relatively small tidal volumes and high ventilation rates. Diseases characterized by airway obstruction have prolonged time constants and are therefore best managed with relatively slow rates and high tidal volumes.

71.1 Mechanical Ventilation

Ashok P. Sarnaik and Christopher Mastropietro

The decision to institute mechanical ventilation is based mainly on the need to assist lung function; supporting left ventricular performance and treating intracranial hypertension are additional indications. Although there are no absolute criteria for derangement of gas exchange, Pao_2 <60 torr while breathing >60% oxygen, $Paco_2$ >60 torr, and pH <7.25 are often reasons to initiate mechanical ventilation. Clinical impressions of fatigue and impending exhaustion are also indications for ventilatory support even in the presence of adequate gas exchange. Positive-pressure ventilation is a powerful means of decreasing left ventricular afterload, and it is used for this purpose in patients with cardiogenic shock resulting from left ventricular dysfunction. Mechanical ventilation is also used in patients whose respirations are unreliable (e.g., unconscious patients, those with neuromuscular dysfunction) and when deliberate hyperventilation is desired, such as in patients with intracranial hypertension.

Mechanical ventilation neither is intended to normalize gas exchange nor is a form of cure. The goals are to maintain sufficient oxygenation and ventilation to ensure tissue viability until the disease process has resolved and to minimize the inevitable complications of the therapeutic intervention itself. Pao_2, $Paco_2$, and pH levels are maintained in ranges that provide a safe environment for the patient while protecting the lungs from damage due to oxygen toxicity, pressure (barotrauma), tidal volume overdistention (volutrauma), atelectrauma, and cytokine release (biotrauma) (Figs. 71-3 and 71-4).

BASIC CONCEPTS OF VENTILATOR MANAGEMENT

Equation of Motion

A pressure gradient is required for air to move from one place to another (Fig. 71-5). During natural spontaneous ventilation, inspiration results from generation of negative intrapleural pressure from

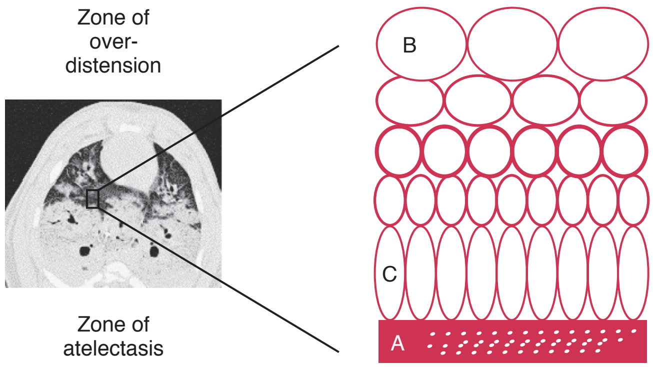

Figure 71-3 **Atelectrauma.** The interface between collapsed and consolidated lung *(A)* and overdistended lung units *(B)* is heterogeneous and unstable. Depending on ambient conditions, this region is prone to cyclic recruitment and derecruitment and localized asymmetric stretch of lung units *(C)* immediately apposed to regions of collapsed lung. *(From Pinhu L, Whitehead T, Evans T, et al: Ventilator-associated lung injury,* Lancet *361:332–340, 2003.)*

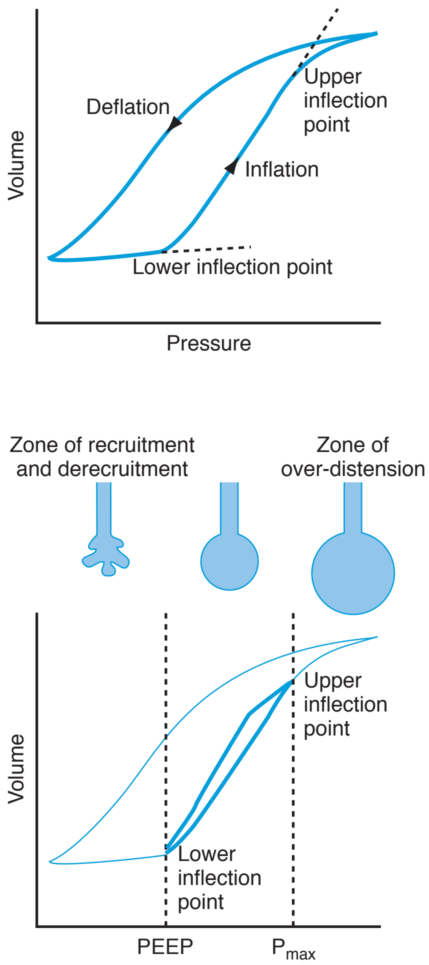

Figure 71-4 **Pulmonary pressure-volume relation in a patient with acute lung injury.** *Top,* The lower inflection point is typically 12-18 cm H_2O, and the upper inflection point 26-32 cm H_2O. *Bottom,* Specific protective ventilation strategies require that positive end-expiratory pressure is set just above the lower inflection point and the pressure limit (P_{max}) just below the upper inflection point. Hence the lung is ventilated in the safe zone between the zone of recruitment and derecruitment and the zone of overdistention, and both high-volume and low-volume injury are avoided. *(From Pinhu L, Whitehead T, Evans T, et al: Ventilator-associated lung injury,* Lancet *361:332–340, 2003.)*

1. Pressure gradient is required to move air from one place to another
2. Movement of air is opposed by flow-resistive and elastic properties of the system

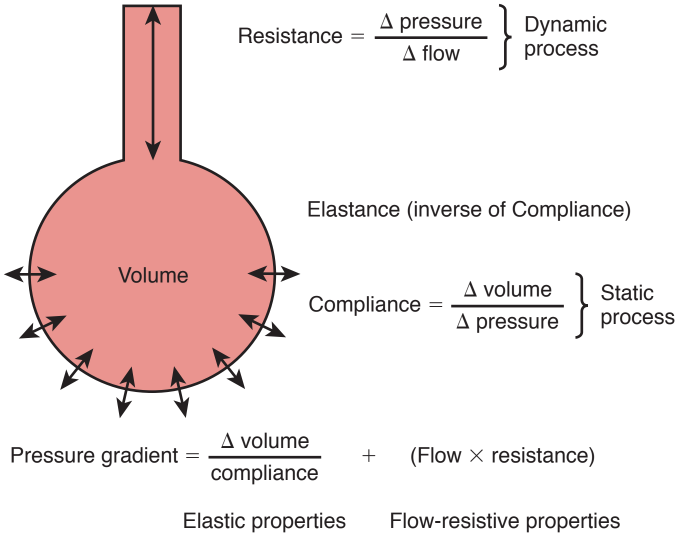

Figure 71-5 **Equation of motion.** A pressure gradient is required to move air from one place to another. In the lungs, the required pressure gradient must overcome the lung and chest wall elastance (static component) and the flow-resistive properties (dynamic component). The static component is increased in alveolar interstitial diseases and stiff chest wall, whereas the dynamic component is increased with airway obstruction.

contraction of the diaphragm and intercostal muscles, drawing air from the atmosphere across the airways into the alveoli. During mechanical ventilation, inspiration results from positive pressure created by compressed gases through the ventilator, which pushes air across the airways into alveoli. In both spontaneous and mechanical ventilation, exhalation results from alveolar pressure generated by the elastic recoil of the lung and the chest wall. Pressure necessary to move a given amount of air into the lung is determined by 2 factors: lung and chest wall elastance, and airway resistance. Figure 71-5 describes the relationship among pressure gradient, compliance, and resistance. *Elastance*—defined as the change in pressure (ΔP) divided by the change in volume (ΔV)—refers to the property of a substance to oppose deformation. It is opposite of *compliance* (ΔV ÷ ΔP), the property of a substance to allow distention or lengthening when subjected to pressure. Compliance (C) is therefore expressed as 1/elastance.

The pressure needed to overcome tissue elastance is measured in conditions in which there is no flow (at end-inspiration and end-expiration) and is therefore a reflection of static conditions in the lung. It is influenced by tidal volume and compliance (P = ΔV ÷ C). It is increased with high tidal volume and low compliance. This pressure gradient is used to calculate the static compliance of the respiratory system (C_{STAT}).

Resistance (R) refers to the opposition to generation of flow. It is measured as the amount of pressure needed to generate a unit of flow (ΔP ÷ ΔFlow). Pressure needed to overcome airway resistance is calculated as flow multiplied by resistance. Because this pressure is needed only when the flow is occurring through the airways, it is referred to as the *dynamic component*. Pressure to overcome flow-resistive properties is measured when there is maximum flow and is therefore under dynamic conditions. It is increased in conditions with greater airway resistance and flow rate. Flow rate depends on the time allowed for inspiration and expiration. At higher respiratory rates, there is less time available for each inspiration and expiration, necessitating higher flows; therefore higher pressure is required to overcome flow-resistive properties. The pressure gradient necessary to move air from one place to another is the sum of pressure needed to overcome the elastic and flow-resistive properties of the lung. This pressure gradient is taken into

account to calculate the dynamic compliance of the respiratory system (C_{DYN}). The difference in change in pressure between static conditions and dynamic conditions is attributable to airway resistance.

Functional Residual Capacity

Also see Chapter 373.

During inspiration, oxygen-enriched gas enters alveoli. During exhalation, oxygen continues to be removed by the pulmonary capillary circulation. *FRC* is the volume of gas left in the alveoli at the end of expiration. It is the only source of gas available for gas exchange during exhalation. In diseases with decreased FRC (e.g., ARDS, pulmonary edema), alveolar oxygen concentration declines sharply throughout expiration, resulting in hypoxemia. Two ventilator strategies commonly employed to improve oxygenation in such situations are the application of PEEP and increasing the inspiratory time (Tɪ) (Fig. 71-6). PEEP increases FRC, whereas a longer Tɪ allows longer exposure of pulmonary capillary blood to a higher concentration of O_2 during inspiration.

Time Constant

At the beginning of inspiration, the atmospheric pressure is higher than the pressure in the alveoli, resulting in movement of air into the

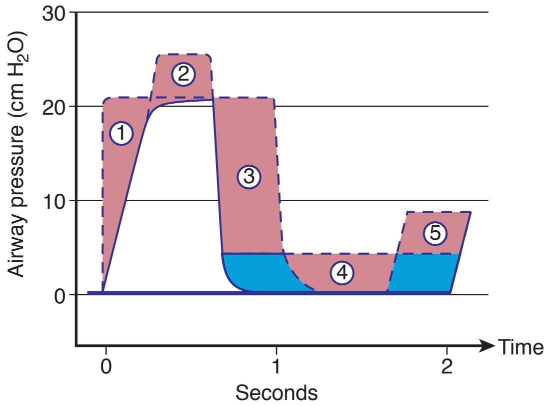

Figure 71-6 Five different ways to increase mean airway pressure: *(1)* Increase the respiratory flow rate, producing a square wave inspiratory pattern; *(2)* increase the peak inspiratory pressure; *(3)* reverse the inspiratory-expiratory ratio or prolong the inspiratory time without changing the rate; *(4)* increase positive end-expiratory pressure; and *(5)* increase the ventilatory rate by reducing the expiratory time without changing the inspiratory time. *(From Harris TR, Wood BR: Physiologic principles. In Goldsmith JP, Karotkin EH, editors:* Assisted ventilation of the neonate, *ed 3. Philadelphia, 1996, WB Saunders.)*

alveoli. During mechanical ventilation, the ventilator circuit serves as the patient's atmosphere. As alveoli expand with air, the alveolar pressure rises throughout inspiration until it equilibrates with the ventilator pressure, at which time airflow ceases. Expiration starts when the ventilator pressure falls below the alveolar pressure. Alveolar pressure decreases throughout expiration until it reaches the ventilator pressure, at which time no further egress of air from the alveoli occurs. If inspiration or expiration is terminated before pressure equilibration between alveoli and the ventilator is allowed to occur, alveolar expansion during inspiration or alveolar emptying during expiration is incomplete. Incomplete inspiration results in delivery of decreased tidal volume, whereas incomplete expiration is associated with air trapping and the presence of residual PEEP in the alveoli that is greater than the ventilator pressure, referred to as *auto-PEEP*. Some time is required for pressure equilibration to occur between alveoli and the atmosphere, which is reflected in the *time constant* (TC). It takes 3 TCs for 95%, and 5 TCs for 99%, of pressure equilibration to occur. The TC depends on compliance and resistance, and their relationship is depicted in Figure 71-7. TC is calculated as compliance multiplied by resistance ($C \times R$) and is measured in seconds.

Diseases with decreased compliance (increased elastance) are characterized by high elastic recoil pressure, which results in more rapid equilibration of alveolar and ventilator pressures, thereby decreasing TC. Diseases with increased airway resistance are associated with slower flow rates, require longer time for movement of air from one place to another, and therefore have increased TC. Airways expand during inspiration and narrow during expiration (see Chapter 373). Therefore, expiratory time constant (TCᴇ) is longer than inspiratory time constant (TCɪ). In intrathoracic airway obstruction (asthma, bronchiolitis, aspiration syndromes), airway narrowing is much more pronounced during expiration. Therefore, although both TCᴇ and TCɪ are prolonged in such diseases, TCᴇ is much more prolonged than TCɪ. Patients with such diseases therefore are best ventilated with slower rates, higher tidal volume, and longer expiratory time than inspiratory time. In diseases characterized by decreased compliance, both TCᴇ and TCɪ are short; however, the TCᴇ is closer to TCɪ than in normal lungs because of the stiffer alveoli recoil with greater force. Patients with these diseases are best ventilated with small Vᴛ to prevent ventilator-induced lung injury and with a relatively longer inspiratory time in each breath to improve oxygenation.

Critical Opening Pressure

Collapsed or atelectatic alveoli require a considerable amount of pressure to open. Once open, the alveoli require relatively less pressure for continued expansion. The process of opening atelectatic alveoli is called *recruitment*. In a normal lung, alveoli remain open at the end of expiration, and therefore the lung requires relatively less pressure to receive its tidal volume. In a disease process in which the alveoli

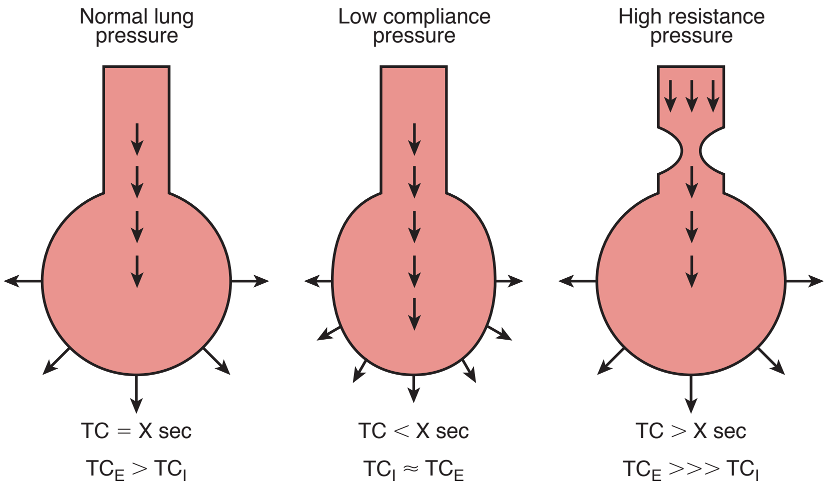

Figure 71-7 Time constant (TC). A certain amount of time is necessary for pressure equilibration (and therefore completion of delivery of gas) to occur between proximal airway and alveoli. TC, a reflection of time required for pressure equilibration, is a product of compliance and resistance. In diseases of decreased lung compliance, less time is needed for pressure equilibration to occur, whereas in diseases of increased airway resistance, more time is required. Expiratory TC is increased much more than inspiratory TC in obstructive airway diseases, because airway narrowing is exaggerated during expiration.

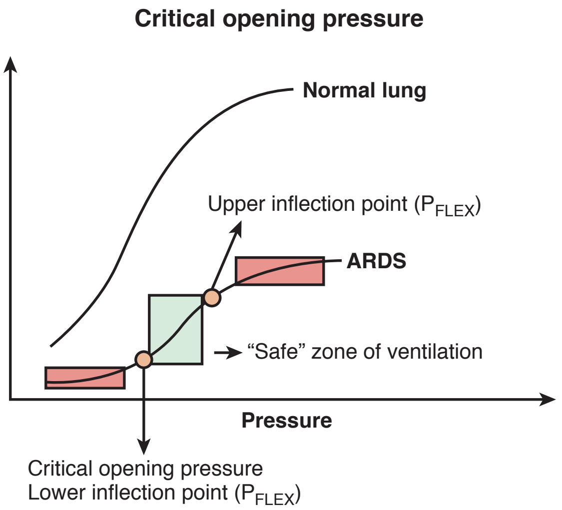

Figure 71-8 **Volume-pressure relationship in normal lung and in ARDS.** In ARDS, atelectatic alveoli require a considerable amount of pressure to open. Critical opening pressure, also referred to as lower P_{FLEX}, is the airway pressure above which further alveolar expansion occurs with relatively less pressure. Upper P_{FLEX} is the airway pressure above which further increase in pressure results in less alveolar expansion; this is the area of alveolar overdistention. Keeping tidal volume between upper and lower P_{FLEX} values is considered less injurious to the lung.

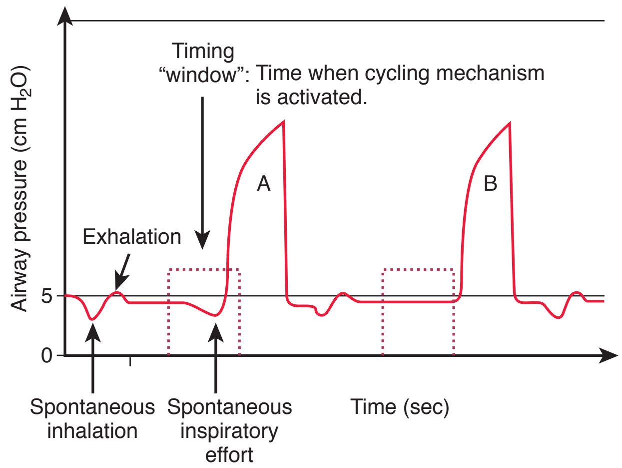

Figure 71-9 **Synchronized intermittent mandatory ventilation.** At set intervals, the ventilator's timing circuit becomes activated and a timing "window" appears *(dotted line area).* If the patient initiates a breath in the timing window, the ventilator delivers a mandatory breath. If no spontaneous effort occurs, the ventilator delivers a mandatory breath at a fixed time after the timing window. *(From Banner MJ, Gallagher TJ: Respiratory failure in the adult: ventilatory support. In Kirby RR, Smith RA, Desautels DA, editors:* Mechanical ventilation, *New York, 1985, Churchill Livingstone.)*

collapse at the end of expiration (e.g., ARDS), a substantial amount of pressure is required to open the alveoli during inspiration. This pressure causes ventilator-induced lung injury via 2 mechanisms: (1) barotrauma at the terminal airway–alveolar junction and (2) volutrauma as a result of overdistention of alveoli that are already open (see Figs. 71-3 and 71-4). Although a pulmonary parenchymal disease process is rarely uniform, and each of the millions of alveoli may have its own mechanical characteristics, a composite volume-pressure relationship could be conceptualized for the whole lung (Fig. 71-8).

In these situations, the lower and upper portions of the curve are relatively horizontal, and the middle portion is more vertical. At the beginning of inspiration, atelectatic alveoli are being recruited, requiring high pressure for a relatively small increase in volume. Once they are recruited, further increase in volume requires relatively less pressure. The pressure at which most alveoli are open is called *critical opening pressure*; this point is also referred to as the *lower inflection point* (lower P_{FLEX}). After the lower P_{FLEX}, greater volume can be delivered for relatively less pressure until the upper P_{FLEX} is reached, at which the volume-pressure curve again becomes relatively horizontal. The goal of mechanical ventilation in alveolar interstitial pathology is to deliver a tidal volume between the lower and upper inflection points, the so-called safe zone of ventilation. If V_T is delivered with a change in inflation pressure that includes the lower P_{FLEX}, alveoli are likely to open *and* close during every breath, a process termed *tidal recruitment* that is injurious to the lung, especially at the terminal airway–alveolar junction. If V_T is delivered with a change of pressure that includes the upper P_{FLEX}, overdistention of alveoli is likely to occur, resulting in volutrauma and barotrauma. Keeping tidal ventilation between the upper and lower P_{FLEX} values is accomplished by maintaining a level of PEEP to produce baseline alveolar recruitment and delivering a relatively small (6 mL/kg) V_T. Termed "open lung" strategy, this approach has proved to be beneficial in alveolar interstitial diseases such as ARDS.

PHASES OF MECHANICAL VENTILATION

The planning of a ventilatory strategy must consider the four phases of the respiratory cycle separately, taking into account these patient clinical characteristics: (1) initiation of respiration and a variable that is controlled, often referred to as *mode;* (2) inspiratory phase characteristics, which determine the duration of inspiration and how the pressure or volume is delivered; (3) termination of inspiration, often referred to as *cycle;* and (4) expiratory phase characteristics. Ideally, mechanical ventilation should not completely take over the work of breathing but, rather, should assist the patient's own respiratory effort. In the absence of the patient's effort, respiratory muscle deconditioning may occur, making weaning from mechanical ventilation more difficult.

Initiation of Inspiration and the Control Variable (Mode)

The initiation of inspiration may be set to occur at a predetermined rate and interval regardless of patient effort, or it could be timed in response to patient effort. Once inspiration is initiated, the ventilator breath either is controlled entirely by the ventilator (control mode) or supports the patient's inspiratory effort to a predetermined inspiratory volume or pressure target (support mode). Advances in technology allow for greater patient–ventilator synchrony to occur. The ventilator may be set to be "triggered" by the signal it receives as a result of patient effort. This may be in the form of lowering of either pressure (pressure trigger) or airflow (flow trigger) in the ventilator circuit generated by the patient's inspiratory effort. If no such signal is received because of lack of patient effort, the ventilator delivers a breath at an interval selected by the operator.

Control Modes

Intermittent Mandatory Ventilation Mode

In intermittent mandatory ventilation (IMV), the inspiration is initiated at a set frequency with a timing mechanism independent of patient effort. In between machine-delivered breaths, the patient can breathe spontaneously from a fresh source of gas. IMV allows for adjustment of ventilator support according to the patient's needs, making it useful in the weaning process. Lack of synchrony between machine-delivered breaths and patient efforts may result in ineffective ventilation and patient discomfort, especially when IMV is delivered at a high rate. In such cases, the patient may require sedation and pharmacologic paralysis for efficient delivery of tidal volume. To obviate this problem, *synchronized IMV (SIMV)* is used, whereby the machine-delivered breaths are triggered by the patient's inspiratory efforts (Fig. 71-9). In between the machine-delivered breaths, a fresh source of gas is available for spontaneous patient breaths. In the

absence of patient effort, the patient receives a backup rate much like in IMV mode. Even with SIMV, ventilator–patient asynchrony can occur, because VT, inflation pressure, and inspiratory time are determined by the ventilator alone.

Assist-Control Mode

In assist-control (AC) mode, each and every patient breath is triggered by pressure or flow generated by patient inspiratory effort and "assisted" with either preselected inspiratory pressure or volume. The rate of respirations is therefore determined by the patient's inherent rate. A backup total (patient and ventilator) obligatory rate is set to deliver a minimum number of breaths. On AC mode with a backup rate of 20 breaths/min, all of the breaths of a patient with an inherent respiratory rate of 15 breaths/min will be assisted by the ventilator, and the patient will receive 5 additional breaths/min. On the other hand, a patient with an inherent rate of 25 breaths/min will receive all 25 breaths assisted. Although useful in some patients, the AC mode cannot be used in the weaning process, which involves gradual decrease in ventilator support.

Control Variable

Once initiated, either the tidal volume or the pressure delivered by the machine can be controlled. The machine-delivered breath is thus referred to as either volume-controlled or pressure-controlled (Table 71-11).

With *volume-controlled ventilation* (VCV), machine-delivered volume is the primary control, and the inflation pressure generated depends on the respiratory system's compliance and resistance. Changes in respiratory system compliance and resistance are therefore easily detected from changes observed in inflation pressure. In *pressure-controlled ventilation* (PCV), the pressure change above the baseline is the primary control, and the tidal volume delivered to the lungs depends on the respiratory system's compliance and resistance. Changes in respiratory system compliance and resistance do not affect inflation pressure and may therefore go undetected unless the exhaled VT is monitored. VCV and PCV have their own advantages and disadvantages (see Table 71-11). Generally speaking, PCV is more efficient than VCV in terms of amount of tidal volume delivered for a given inflation pressure during ventilation of a lung that has nonuniform time constants, such as asthma. In VCV, relatively less-obstructed airways are likely to receive more of the machine-delivered volume throughout inspiration than relatively more-obstructed airways with longer time constants (Fig. 71-10*A*). This situation would result in uneven ventilation, higher PIP, and a decrease in dynamic compliance. In PCV, because of a constant inflation pressure that is held throughout inspiration, relatively less-obstructed lung units with shorter time constants would achieve pressure equilibration earlier during inspiration than the relatively more-obstructed areas. Thus, units with shorter TCs would attain their final volume earlier in inspiration, and those with longer TCs would continue to receive additional volume later in inspiration (Fig. 71-10*B*). This situation would result in more even distribution of inspired gas, delivery of more VT for the same inflation pressure, and improved dynamic compliance in comparison with VCV.

Pressure-regulated volume control (PRVC) combines the advantages of VCV and PCV. In this mode, the VT and TI are controlled as primary variables but the ventilator determines the amount of pressure needed to deliver the desired VT. Inflation pressure is thus adjusted to deliver the prescribed VT over the TI, depending on the patient's respiratory compliance and resistance.

Support Modes

Pressure-support ventilation (PSV) and *volume-support ventilation* (VSV) are designed to support the patient's spontaneous respirations. With PSV, initiation of inspiration is triggered by the patient's spontaneous breath, which is then "supported" by a rapid rise in ventilator pressure to a preselected level. The inspiration is continued until the inspiratory flow rate falls to a set level (generally 25% of peak flow rate) as the patient's lungs fill up. Thus, TI is controlled by the patient's own efforts. PSV can be combined with SIMV so that any breath above the SIMV rate is supported by PSV. Allowing the patient to control as much of the rate, VT, and inspiratory time as possible is considered a gentler form of mechanical ventilation than SIMV, in which the VT (or inflation pressure) and TI are preset. PSV as the sole source of mechanical ventilator support is often not adequate for patients with severe lung disease; however, it is especially useful in patients in the process of being weaned and in patients who require mechanical ventilation for relatively minor lung disease or for neuromuscular weakness. VSV is similar to PSV, in that all the spontaneous breaths are supported. In VSV, inspiratory pressure to support spontaneous breaths is adjusted to guarantee a preset VT. If there is a change in respiratory mechanics or patient effort, the inspiratory pressure to support the breath initiated by patient effort is automatically adjusted to deliver the set VT.

Inspiratory Phase Characteristics

TI, inspiratory flow waveform, and pressure rise time can be adjusted in the inspiratory phase to suit the patient's respiratory mechanics.

In PCV, the duration of TI is directly set in seconds. In VCV, the inspiratory time can be adjusted by adjusting the inspiratory flow (volume/time). The choice of TI value depends on the respiratory rate, which determines the total duration of each breath, and on the estimation of inspiratory and expiratory time constants. Decreasing the flow rate delivery increases TI, and vice versa. With an increase in TI, the pulmonary capillary blood is exposed to a higher level of alveolar P_{O_2} for a longer time. This is beneficial in diseases with decreased FRC, such as ARDS and pulmonary edema. An increase in TI also increases

Table 71-11 Characteristics of Pressure-Controlled and Volume-Controlled Methods of Ventilation

	PRESSURE-CONTROLLED VENTILATION	VOLUME-CONTROLLED VENTILATION
Control setting(s)	Inflation pressure Inspiratory time Rise time	VT Flow rate Inspiratory flow pattern (constant vs decelerating)
Machine-delivered volume	Depends on respiratory system compliance and resistance	Constant
Inflation pressure	Constant	Depends on respiratory system compliance and resistance
Endotracheal tube leak	Somewhat compensated	Leaked volume part of VT
Distribution of ventilation	More uniform in lungs with varying time constant units	Less uniform in lungs with varying time constant units
Patient comfort	Possibly compromised	Possibly enhanced
Weaning	Inflation pressure adjustment required to deliver desired VT	VT remains constant, inflation pressure automatically weaned

VT, tidal volume.

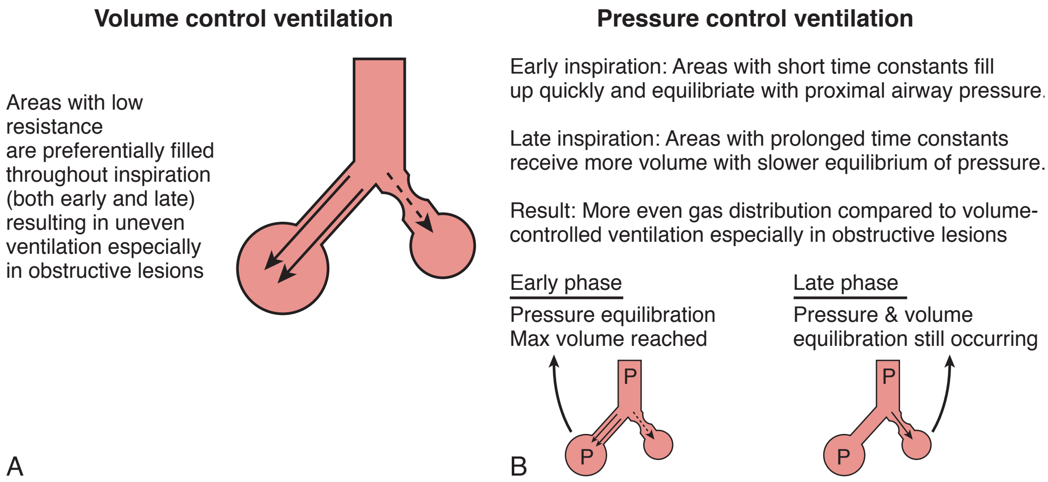

Figure 71-10 *A,* In VCV, VT is delivered to the less-obstructed areas throughout inspiration. Obstructed areas of the lung therefore receive a lower proportion of VT, resulting in uneven ventilation. *B,* In PCV, less-obstructed areas equilibrate with inflation pressure and therefore receive most of their VT early during inspiration. More-obstructed areas, with prolonged time constants, require longer time for pressure equilibration and therefore continue to receive a portion of their VT later during inspiration. The entire VT is more evenly distributed than with volume-cycled ventilation.

VT without increasing inflation pressure in PCV if inspiratory flow is still occurring at the end of expiration. It must be recognized that at a given ventilator rate, an increase in TI decreases expiratory time (TE). Therefore, any strategy that employs an increase in the inspiratory component of the respiratory cycle should ensure that the decreased TE is still sufficient for complete exhalation.

Inspiratory flow waveform can be adjusted in VCV mode as either a constant flow (square waveform) or a decelerating flow (descending ramp waveform). With a square waveform, flow is held constant throughout inspiration. In a descending ramp waveform, the flow is maximum at the start of inspiration and declines throughout its duration. It is debatable which flow pattern is better for a given disease. In PCV and PSV, the prescribed PIP is reached through delivery of airflow. The time required for the ventilator to reach PIP is reflected in the *pressure rise time,* which can be adjusted by control of flow at the beginning of the inspiratory phase. The inspiratory flow rise time is adjusted to provide comfort for a patient who is awake and also to prevent an extremely rapid rise in inspiratory pressure, which might result in barotrauma.

Termination of Inspiration (Cycle)

The two most commonly used inspiratory terminating mechanisms in control modes are time-cycled and volume-cycled. With a time-cycled mechanical breath, inspiration is terminated after a preselected TI has elapsed, whereas with volume-cycled breath, the inspiration ends after a preselected volume has been delivered by the machine into the ventilator circuit. A time-cycled breath is almost always pressure-limited, with the PIP held constant for the duration of inspiration. A volume-cycled breath can be pressure-limited as a safety mechanism to avoid barotrauma. The inspiration-terminating mechanism is set somewhat differently in support modes. In PSV, the inspiration is set to end after the inspiratory flow decreases below a certain percentage (usually 25%) of peak inspiratory flow. This happens when the patient no longer desires to receive additional VT. Such a breath can be termed *flow-cycled*. In volume support mode, inspiration is terminated when the patient has received the desired VT.

Expiratory Phase Maneuvers

The most useful expiratory phase maneuver is the application of PEEP, which is applied to both the control breath and the assisted breath. The most important clinical benefits of PEEP are to recruit atelectatic alveoli and to increase FRC in patients with alveolar–interstitial diseases and thereby improve oxygenation. There is growing recognition that even a brief disconnection from a ventilator, and therefore having zero end-expiratory pressure, can result in significant alveolar derecruitment and decline in oxygenation. In patients with obstructive lesions in which insufficient exhalation results in air trapping and auto-PEEP, extrinsic PEEP (that applied through a mechanical device) can prevent airway closure during expiration and improve ventilation. Other salutary effects of PEEP include redistribution of extravascular lung water away from gas-exchanging areas, improved ventilation–perfusion relationship, and stabilization of the chest wall. The effect of PEEP on lung compliance is variable, depending on the level of PEEP provided and the patient's pulmonary mechanics. By shifting the VT ventilation to a more favorable part of the pressure-volume curve, PEEP may recruit more alveoli, delay airway closure, and improve lung compliance. Excessive PEEP, on the other hand, may lead to overdistention of alveoli and reduced compliance. The effect of PEEP in individual patients can be ascertained by measuring exhaled VT and calculating dynamic compliance. Other deleterious effects of PEEP include decreased venous return, increased pulmonary vascular resistance, and decreased cardiac output.

ADDITIONAL VENTILATORY MODALITIES

Airway Pressure Release Ventilation

Airway pressure release ventilation (APRV) improves oxygenation in cases of severe hypoxemic respiratory failure resulting from alveolar-interstitial disease. This modality applies a CPAP, designated $CPAP_{HIGH}$, to recruit and maintain FRC with brief intermittent release phases of $CPAP_{LOW}$ to allow alveolar gas to escape. $CPAP_{HIGH}$ is analogous to PIP, and $CPAP_{LOW}$ is similar to setting PEEP. In contrast to the patient receiving conventional mechanical ventilation, a patient receiving APRV spends the majority of time in the $CPAP_{HIGH}$ phase, which may last as long as 3-5 sec with a brief (0.3-0.5 sec) time in the $CPAP_{LOW}$ phase. These atypically long inspiratory times are tolerated because of a floating expiratory valve in the ventilator circuit that permits spontaneous breathing during $CPAP_{HIGH}$ phase. Therefore, even if $CPAP_{HIGH}$ phase can be considered inspiratory and $CPAP_{LOW}$ phase can be considered expiratory as far as the ventilator is concerned, the patient is able to breathe spontaneously during both of these phases. The longer ventilator inspiratory times recruit lung units, and the ability to breathe spontaneously during this phase allows distribution of gas flow to atelectatic lung regions. The outcome benefit of APRV in pediatric hypoxemic respiratory failure has not been proven.

High-Frequency Ventilation

Mechanical ventilation at supraphysiologic rates and low tidal volumes, known as high-frequency ventilation (HFV), improves gas

exchange in a selected group of patients who show no response to traditional ventilatory modalities. The mechanism of alveolar ventilation in HFV is very different from that in conventional ventilation, in that HFV is less dependent on VT and more dependent on asymmetric velocities and convective dispersion of inspired gas. Patients with severe persistent hypoxic failure are most likely to benefit from HFV. HFV is also helpful in patients with bronchopleural fistula and persistent air leaks. The main tenet of HFV is to recruit lung volume with a high MAP and produce smaller fluctuations in alveolar pressure during inspiration and expiration, thus maintaining a satisfactory FRC and reducing alveolar stretch. The 2 most investigated techniques of HFV are high-frequency oscillation (HFO) and high-frequency jet ventilation (HFJV).

The most commonly used HFV modality is HFO, which employs a mechanism to generate to-and-fro air movement. Additional air is dragged in (entrained) through a parallel circuit via a Venturi effect. Air is pushed in during inspiration and actively sucked out during expiration. The main determinants of oxygenation are FIO_2 and MAP, whereas ventilation is determined by changes in pressure (amplitude) from the MAP. Commonly used respiratory frequency varies from 5 Hz (300 breaths/min) in adults and older children, to 6-8 Hz (360-480 breaths/min) in young children, 8-10 Hz (480-600 breaths/min) in infants, and 10-12 Hz (600-720 breaths/min) in newborn and premature babies.

In HFJV, a high-frequency interrupter is interposed between a high-pressure gas source and a small cannula that is incorporated in the endotracheal tube (ET). The cannula propels tiny amounts of gas (jets) at high velocity and high frequency through the ET. An additional amount of gas is entrained from a parallel circuit. Unlike in HFO, expiration occurs passively in HFJV as a result of elastic recoil of the lung and the chest wall. PEEP is set through the parallel circuit by a conventional ventilator in line. Respiratory rate is generally set at 420 breaths/min. Major determinants of oxygenation are FIO_2 and PEEP, and the major determinant of ventilation is PIP.

CONVENTIONAL VENTILATOR SETTINGS

FIO_2

The shape of the hemoglobin–oxygen dissociation curve dictates that oxygen content in the blood is not linearly related to PaO_2. A PaO_2 value that results in an oxyhemoglobin saturation of 95% is reasonable in most situations, because a higher PaO_2 would cause minimal increase in arterial oxygen content, and a modest (≈10 torr) drop in PaO_2 would result in minimal decrease in oxyhemoglobin saturation. In most cases, a PaO_2 value of 70-75 torr is a reasonable goal. FIO_2 values that are higher than those necessary to attain oxyhemoglobin saturations of 95% expose the patient to unnecessary oxygen toxicity. Whenever possible, FIO_2 values should be decreased to a level ≤0.4 as long as oxyhemoglobin saturation remains 95% or above.

Mode

The choice of mode of ventilation depends on how much ventilator–patient interaction is desired and the disease entity that is being treated. SIMV or AC is chosen as the control mode, PCV, VCV, or PRVC is chosen as the variable that is to be controlled, and pressure support and volume support are the choices for support modes.

Tidal Volume and Rate

As previously discussed, alveolar ventilation, the chief determinant of $PaCO_2$, is calculated using VT, respiratory rate, and dead space volume. A change in VT results in a corresponding change in VA without affecting the dead space ventilation. A change in respiratory rate will affect the VA as well as the dead space ventilation. As mentioned earlier, the choice of VT and rate depends on the time constant. In a patient with relatively normal lungs, an age-appropriate ventilator rate and a VT of 7-10 mL/kg would be appropriate initial settings. Diseases associated with decreased time constants (decreased static compliance, e.g., ARDS, pneumonia, pulmonary edema) are best treated with small (6 mL/kg) VT and relatively rapid rates (25-40 breaths/min). Diseases associated with prolonged TCs (increased airway resistance, e.g., asthma, bronchiolitis) are best treated with relatively slow rates and higher (10-12 mL/kg) VT. In PCV, the delivered VT depends on the compliance and resistance of the patient's respiratory system and needs to be monitored to ensure the appropriate amount for a given situation. An inflation pressure of 15-25 cm H_2O is sufficient for most patients, but it may need adjustment, depending on the amount of exhaled VT observed. It should be emphasized that achieving a "normal" $PaCO_2$ value is not a goal of mechanical ventilation. Mild hypercapnia (permissive hypercapnia) should be acceptable, especially when one is attempting to limit injurious inflation pressures or VTs.

Inspiratory Time and Expiratory Time

Inspiratory time and expiratory time are adjusted by setting inspiratory flow rate in VCV and by setting the precise TI in PCV. Increasing the inspiratory time results in an increase in MAP, improvement in oxygenation in diseases with decreased FRC, and better distribution of VT in obstructive lung disease. Sufficient expiratory time must be provided to ensure adequate emptying of the alveoli.

Positive End-Expiratory Pressure

The best level of PEEP depends on the disease entity that is being treated, and it may change in the same patient from time to time. Decisions are often based on the PaO_2/FIO_2 ratio and the measurement of dynamic compliance.

PATIENT-VENTILATOR ASYNCHRONY

Patient–ventilator asynchrony occurs when the patient's respiratory pattern does not match that of the ventilator. This can occur during all phases of respiration. Adverse effects of patient- ventilator asynchrony include wasted effort, ineffective delivery of desired VT, excessive generation of intrathoracic pressure resulting in barotrauma and adverse effects on cardiac output, increased work of breathing, and patient discomfort. Although several mechanisms exist to facilitate patient–ventilator asynchrony, a certain amount of asynchrony is inevitable unless the patient is pharmacologically sedated and paralyzed.

Triggering the Ventilator

The patient must be able to trigger the ventilator without excessive effort. Ventilators can be pressure-triggered or flow-triggered. With pressure triggering, the inspiratory valve opens and flow is delivered when a set negative pressure is generated within the patient–ventilator circuit during both inspiration and expiration. The amount of pressure required to trigger an inspiration depends on the pressure trigger sensitivity. In flow triggering, the ventilator provides a base flow of gas through the ventilator–patient circuit. When a flow sensor on the expiratory limb of the patient–ventilator circuit detects a decrease in flow as a result of the patient's inspiratory effort, the inspiratory valve opens and a ventilator breath is delivered. The degree of change in flow required to trigger an inspiration depends on the flow trigger sensitivity. Flow triggering is considered to be more comfortable, primarily because the patient receives some flow prior to triggering the ventilator, in contrast to pressure triggering, in which no flow is provided until the ventilator breath is triggered. Increasing the trigger sensitivity by decreasing the change in either pressure or flow needed to trigger an inspiration decreases the work of breathing. However, reducing the required pressure or flow excessively could result in accidental triggering and unwanted breaths by turbulence caused by condensation in the ventilator circuit, ET leaks, or cardiac oscillations.

Selection of Appropriate Inspiratory Time

The duration of TI should match the patient's own inspiratory phase. If TI is too long, the patient's drive to exhale may begin before the ventilator breath has cycled off. When this occurs, exhalation occurs against inspiratory flow and a closed exhalation valve, resulting in increased work of breathing, excessive rise in intrathoracic pressure, and discomfort. If TI is too short, the patient may be still inhaling without respirator support. In general terms, TI is usually initiated at 0.5-0.7 sec for neonates, 0.8-1 sec in older children, and 1-1.2 sec for adolescents and adults. Adjustments need to be made through

individual patient observations and according to the type of lung disease present. In patients with severe lung disease (both obstructive and restrictive), unnatural TI and TE values may have to be selected, as discussed earlier. In such situations, adequate analgesia, sedation, and, in extreme cases, neuromuscular blockade may be needed.

Selection of Inspiratory Flow Pattern

In VCV, inappropriate flow may be another source of patient–ventilator dyssynchrony. After initiation of inspiration, if the set amount of flow is inadequate to meet patient demand, a state of "flow starvation" occurs, resulting in excessive work of breathing and discomfort. Such cases may require a decelerating inspiratory flow pattern, in which a higher flow is provided in the beginning of inspiration and less toward the end as the lungs fill up. On the other hand, such a pattern may be uncomfortable for a patient who desires more gradual alveolar filling. The selection of inspiratory flow pattern should be based on the individual patient's respiratory mechanics. In PCV and PSV, the inspiratory rise time determines the manner in which the airway pressure is raised and VT delivered. Considerations for choosing the appropriate rise time in PCV and PSV are similar to those for choosing the inspiratory flow pattern in VCV.

Use of Support Modes

As much as possible, a conscious patient should be allowed to have spontaneous breaths that are supported by either PSV or VSV. This approach minimizes the mandatory breaths generated by the ventilator that are beyond the patient's control to modulate. Therefore, continued assessments should be made to determine whether the patient is able to maintain ventilatory requirements more in support modes and less in control modes.

Use of Sedation and Pharmacologic Paralysis

Having a conscious but comfortable patient is a desirable goal during mechanical ventilation. Spontaneous breaths with good muscle tone and presence of cough are important for adequate clearance of tracheobronchial secretions. The patient's ability to indicate distress is also important in identifying and preventing potential injurious factors. In certain situations, management of patient–ventilator asynchrony assumes far greater importance when the asynchrony is causing unacceptable derangement of gas exchange and ventilator-induced lung injury. Both alveolar interstitial lung pathology and obstructive airway diseases may necessitate unnatural and uncomfortable settings for respiratory rate, TI, and inflation pressures. In such situations, deep sedation is often necessary. Benzodiazepines and opiates are the agents most commonly used for this purpose. In extreme situations, pharmacologic paralysis with a nondepolarizing agent, such as vecuronium, is required to abolish any patient effort and respiratory muscle tone. When pharmacologic paralysis is used, deep sedation must be ensured so that the patient does not sense pain and discomfort. Pharmacologic sedation and paralysis can ensure total control of the patient's ventilation by mechanical means and may result in lifesaving improvement in gas exchange with reduction in inflation pressures. However, long-term use of such agents may be associated with undesirable consequences and higher morbidity. The risk of inadequate tracheobronchial secretions and atelectasis is potentially greater. Long-term use of pharmacologic sedation may be associated with chemical dependency and withdrawal manifestations, and prolonged neuromuscular blockade is associated with neuromyopathy in critically ill patients. The benefits of sedation and pharmacologic paralysis therefore should be carefully balanced with the risks, and periodic assessments should be made to determine the need for their continuation.

Cardiopulmonary Interactions

Mechanical ventilation can have both salutary as well as adverse effects on cardiac performance. By decreasing oxygen consumption necessary for work of breathing, oxygen supply to vital organs is improved. Positive-pressure breathing decreases left ventricular afterload, thus enhancing stroke volume and cardiac output in patients with failing myocardium (e.g., myocarditis). On the other hand, the decreased systemic venous return may further compromise stroke volume in hypovolemic patients. Such patients will require intravascular fluid loading. Also an increase in pulmonary vascular resistance (PVR) as a result of positive intrathoracic pressure may result in further decompensation of a poorly performing right ventricle. PVR is at its lowest value at an optimum FRC. When FRC is too low or too high, PVR (and therefore the right ventricular afterload) is increased. Both desirable and undesirable effects of cardiopulmonary interactions may coexist and require ongoing assessment and necessary interventions.

MONITORING RESPIRATORY MECHANICS

Exhaled Tidal Volume

Exhaled tidal volume (VTE) is measured by a pneumotachometer in the ventilator circuit during exhalation. In VCV, part of the machine-delivered volume may leak out during inspiration and therefore never reach the patient. Measurement of VTE more accurately describes the VT that is contributing to the patient's alveolar ventilation. In PCV, the VTE depends on the patient's respiratory system compliance and resistance, and therefore offers valuable diagnostic clues. A decrease in VTE during PCV is indicative of either decrease in compliance or increase in resistance and is helpful in directing the clinician to appropriate investigation and management. An increase in VTE is indicative of improvement and may require weaning of inflation pressures to adjust the VTE.

Peak Inspiratory Pressure

In VCV and PRVC, the PIP is the secondary variable determined by the patient's respiratory system compliance and resistance. An increase in PIP in these modes is indicative of decreased compliance (e.g., atelectasis, pulmonary edema, pneumothorax) or increased resistance (e.g., bronchospasm, obstructed ET). During VCV and PRVC, decreasing the respiratory rate or prolonging the TI will result in a lower PIP in patients with prolonged time constants because more time will be available for alveoli to fill. In such patients, a decrease in PIP suggests increased compliance or decreased resistance of the respiratory system.

Respiratory System Dynamic Compliance and Static Compliance

The changes in PIP during VCV and PRVC, and in VTE during PCV, are determined by C_{DYN} of the respiratory system (lung and chest wall). Dynamic compliance is calculated as follows:

$$C_{DYN} = V_{TE} \div (PIP - PEEP)$$

It takes into account both the flow-resistive and the elastic properties of the respiratory system. Changes in C_{DYN} can be used to assess effects of different levels of PEEP as tidal ventilation is shifted along the slope of the volume-pressure curve (see Fig. 71-8). An increase in PEEP in alveolar-interstitial diseases (increased elastance), resulting in an increase in C_{DYN} suggests alveolar recruitment, whereas a decrease in C_{DYN} may indicate overdistention. Similarly, in obstructive diseases (increased resistance), adjustment in PEEP levels to ameliorate airway collapse during exhalation can be guided by monitoring C_{DYN}. To assess only the elastic recoil of the lung, measurement of C_{STAT} when there is no airflow is required. This measurement is performed by using an inspiratory hold maneuver with the patient under neuromuscular blockade and observing pressure-time and flow-time waveforms (Fig. 71-11). During this maneuver, inspiratory flow ceases while the expiratory valve continues to remain closed, thus allowing pressure to equilibrate throughout the ventilator circuit and the patient's lungs. This pressure, referred to as the *plateau pressure* (P_{plat}), is reflective of alveolar pressure. C_{STAT} is calculated as follows:

$$C_{STAT} = V_{TE} \div (P_{plat} - PEEP)$$

The difference between C_{DYN} and C_{STAT} is attributable to airway resistance. This difference is minimal in alveolar-interstitial diseases but substantial in airway obstruction.

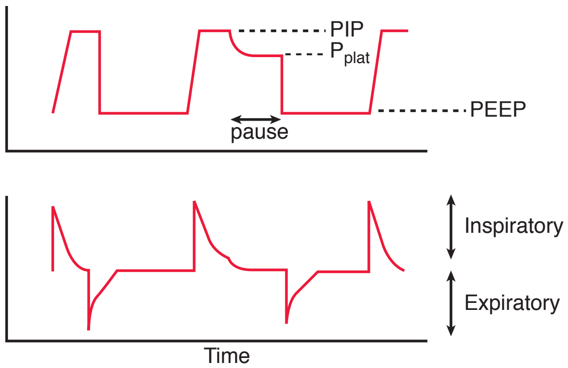

Figure 71-11 Alveolar pressure is best determined by measurement of plateau pressure (P_{plat}). Inspiration is paused for an extended period, and alveolar gas pressure is allowed to equilibrate with the ventilator circuit pressure. Airway pressure at the end of the inspiratory pause is P_{plat}. The difference between peak inspiratory pressure (PIP) and P_{plat} is to overcome flow-resistive properties of the lung, whereas P_{plat} reflects the pressure needed to overcome elastic properties of lung and chest wall.

Assessment of Auto-PEEP

Auto-PEEP is assessed with the use of an expiratory pause maneuver in which inspiration is delayed and alveolar pressure is allowed to equilibrate with the airway. In diseases with airway obstruction, insufficient alveolar emptying may occur if exhalation time is not adequate. The alveolar pressure in excess of the set PEEP at the completion of the expiratory pause is measured as auto-PEEP or intrinsic PEEP. Auto-PEEP can have adverse effects on ventilation and hemodynamic status. It can be managed by decreasing the respiratory rate or inspiratory time and thus allowing greater time for exhalation. Auto-PEEP may also be managed by increasing the set PEEP ("extrinsic" PEEP), thereby delaying airway closure during exhalation and improving alveolar emptying.

Assessment of Dead Space Ventilation

Positive pressure ventilation and application of PEEP may result in a decrease in venous return, cardiac output, and, therefore, also the pulmonary perfusion. Ventilation of poorly perfused alveoli results in dead space ventilation, which does not contribute to gas exchange. The dead space–V_T fraction can be calculated with the following equation:

$$V_D/V_T = (PaCO_2 - PECO_2) \div PaCO_2$$

Normal V_D/V_T is 0.33. Increased V_D/V_T is indicative of poorly perfused alveoli. Patients with increased V_D/V_T may require intravascular volume infusion or other means of augmenting the cardiac output to improve pulmonary perfusion. The V_D/V_T fraction is calculated and displayed by commercially available capnographs, which measure endotracheal P_{CO_2} continuously.

VENTILATOR-INDUCED LUNG INJURY

Like most medical therapies, mechanical ventilation can be harmful if appropriate principles are not followed. Lung volumes that are too high or too low should be avoided. In attempting to recruit and maintain FRC, the clinician must be careful not to overdistend alveoli. Excessive PIP and V_T can lead to unwelcome stress and strain on alveolar walls. This volutrauma and barotrauma can lead to disruption of tight junctions between alveolar epithelial and capillary endothelial cells, causing fluid and protein transudation in the alveoli. Inflammatory mediators and cytokines are released, exacerbating the injury and promoting exudative fluid formation. Decreased production and inactivation of surfactant result in atelectasis and further impairment of gas exchange. Evidence shows that in patients with severe acute hypoxemic respiratory failure, avoidance of $V_T \geq 10$ mL/kg and $P_{plat} \geq 30$ cm H_2O limits diffuse alveolar damage.

Insufficient PEEP is another important mechanism of ventilator-induced lung injury. Alveoli that are recruited during inspiration must remain open during expiration; if they do not, atelectrauma occurs, which is defined as undesirable shear stress on alveolar walls as they are opened and closed repeatedly. Therefore, the ideal PEEP for a patient should maximize the number of open alveoli and minimize the number of overdistended alveoli. Careful adjustments of PEEP may also permit the clinician to wean a patient from a high inspired oxygen concentration, another potential source of lung injury (oxytrauma). Though most patients receive an inspired oxygen concentration of 100% during endotracheal intubation and at the beginning of mechanical ventilation, increasing PEEP to recruit alveoli without overdistention should be quickly instituted to improve oxygenation and permit weaning of the F_{IO_2}. Although an F_{IO_2} value below which there is no risk of oxygen toxicity is unknown, most clinicians aim for a value <0.6.

Ventilator-Associated Pneumonia

The pathophysiology of ventilator-associated pneumonia (VAP) is multifactorial. Aspiration of oral and/or gastric secretions, colonization of ETs, and suppression of cough reflexes with sedation all play a role. New-onset fever and leukocytosis accompanied by demonstration of an infiltrative process by chest radiographs are consistent with a diagnosis of VAP. This complication can lead to worsened gas exchange, increased duration of ventilation, and even death. Elevation of the head of the bed to 30 degrees after initiation of mechanical ventilation and use of a protocol for oral decontamination during mechanical ventilation are two means of reducing the risk for VAP. The most effective strategy to minimize any of the aforementioned complications is regular assessment of extubation readiness and liberation from mechanical ventilation as soon as clinically possible.

Weaning

Weaning from mechanical ventilation should be considered as a patient's respiratory insufficiency begins to improve. Most pediatricians favor gradual weaning from ventilator support. With SIMV, the ventilator rate is slowly reduced, allowing the patient's spontaneous breaths (typically assisted with pressure or volume support) to assume a larger proportion of the minute ventilation. When the ventilator rate is low (<5 breaths/min) such that its contribution to minute ventilation is minimal, assessment of extubation readiness is performed. An alternative method of gradual weaning is transition to a pressure support mode of ventilation. In this mode, no ventilator rate is set, allowing all triggered breaths to be assisted with pressure support. The clinician reduces the pressure support slowly to a low value (<5-10 cm H_2O), at which point assessment of extubation readiness is performed. During either technique, weaning should be halted if tachypnea, increased work of breathing, hypoxemia, hypercapnia, acidosis, diaphoresis, tachycardia, or hypotension occurs.

The most objective means of assessing extubation readiness is a spontaneous breathing trial (SBT). Prior to performance of an SBT, a patient should be awake with intact airway reflexes, capable of handling oropharyngeal secretions, and with stable hemodynamic status. In addition, gas exchange should be adequate, defined as a Pa_{O_2} >60 mm Hg while receiving an F_{IO_2} <0.4 and PEEP ≤5 cm H_2O. If these criteria are present, a patient should be started on CPAP with minimal or no pressure support (≤5 cm H_2O). If this SBT is tolerated with no episodes of respiratory or cardiovascular decompensation, successful extubation is likely. Some neonates and small children cannot be calmed or consoled long enough to complete the SBT. In this situation, extubation readiness must be assessed on a low level of ventilator support. Data suggest that there is a low risk of extubation failure if the patient is comfortable and has stable hemodynamic status with adequate gas exchange and spontaneous V_T >6.5 mL/kg while receiving <20% of total minute ventilation from the ventilator. Certain patient populations are at increased risk for extubation failure, such as young infants, children mechanically ventilated for >7 days, and patients with chronic respiratory or neurologic conditions. These children often benefit from transition to a noninvasive form of positive pressure ventilation (e.g., high-flow nasal cannula, CPAP, or BiPAP)

delivered via nasal prongs or face mask to increase the odds of successful extubation. The likelihood of postextubation upper airway obstruction, the most common cause of extubation failure in children, cannot be predicted on the basis of an SBT result or bedside measurements of physiologic variables. Traumatic endotracheal intubation and subglottic swelling from the ET irritation, especially in patients who exhibit agitation while receiving mechanical ventilation, are common causes of airway narrowing after extubation. Administration of intravenous corticosteroids (dexamethasone 0.5 mg/kg every 6 hr for 4 doses prior to extubation) has been shown to minimize the incidence of postextubation airway obstruction. In patients in whom postextubation airway obstruction develops, the need for re-intubation may be obviated by administration of nebulized racemic epinephrine and heliox.

Chapter 72

Acute Care of the Victim of Multiple Trauma

Cindy Ganis Roskind, Peter S. Dayan, and Bruce L. Klein

EPIDEMIOLOGY

Injury is a leading cause of death and disability in children throughout the world (see Chapter 5.1). According to the World Health Organization report on child injury prevention, unintentional injuries are one of the leading causes of death in children younger than 20 yr and the leading cause of death in children between 10 and 20 yr of age in the world. Road traffic–related injuries, drowning, fire-related events, and falls rank among the top causes of death and disability in children. In Asia, injury accounts for more than 50% of deaths in children <18 yr, with drowning accounting for approximately half. In the United States, more than 12,000 children die each year secondary to unintentional injury, with motor vehicle–related injuries being the leading cause.

Deaths represent only a small fraction of the total trauma burden. Approximately 9.2 million children are treated in U.S. emergency departments (EDs) each year for injury, most commonly for falls. Many survivors of trauma have permanent or temporary functional limitations. Motor vehicle–related injuries and falls rank among the top 15 causes of disability-adjusted life years in children worldwide.

Trauma is frequently classified according to the number of significantly injured body parts (≥1), the severity of injury (mild, moderate, or severe), and the mechanism of injury (blunt or penetrating). In childhood, blunt trauma predominates, accounting for the majority of injuries. In adolescence, penetrating trauma increases in frequency, accounting for approximately 15% of injuries, and has a higher case fatality rate.

REGIONALIZATION AND TRAUMA TEAMS

Mortality and morbidity rates have decreased in geographic regions with comprehensive, coordinated trauma systems. Treatment at designated trauma centers is associated with decreased mortality. At the scene of injury, paramedics should administer necessary advanced life support and perform triage (Fig. 72-1; Tables 72-1 and 72-2). It is usually preferable to bypass local hospitals and rapidly transport a seriously injured child directly to a pediatric trauma center (or a trauma center with pediatric commitment). Children have lower mortality rates after severe blunt trauma when they are treated in designated pediatric trauma centers or in hospitals with pediatric intensive care units.

Table 72-1	Changes in 2011 Guidelines for Field Triage of Injured Patients Compared with 2006 Guidelines

Step One: Physiologic Criteria
- Changed GCS <14 to GCS ≤13
- Added "or need for ventilatory support" to respiratory criteria

Step Two: Anatomic Criteria
- Changed "all penetrating injuries to head, neck, torso and extremities proximal to elbow and knee" to "all penetrating injuries to head, neck, torso and extremities proximal to elbow or knee"
- Changed "flail chest" to "chest wall instability or deformity (e.g., flail chest)"
- Changed "crushed, degloved, or mangled extremity" to "crushed, degloved, mangled, or pulseless extremity"
- Changed "amputation proximal to wrist and ankle" to "amputation proximal to wrist or ankle"

Step Three: Mechanism-of-Injury Criteria
- Added "including roof" to intrusion criterion

Step Four: Special Considerations
- Added the following to older adult criteria
  - SBP <110 might represent shock after age 65 yr
  - Low-impact mechanisms (e.g., ground-level falls) might result in severe injury
- Added "patients with head injury are at high risk for rapid deterioration" to anticoagulation and bleeding disorders criterion
- Removed "end-stage renal disease requiring dialysis" and "time-sensitive extremity injury"

Transition Boxes
- Changed layout of the figure
- Modified specific language of the transition boxes

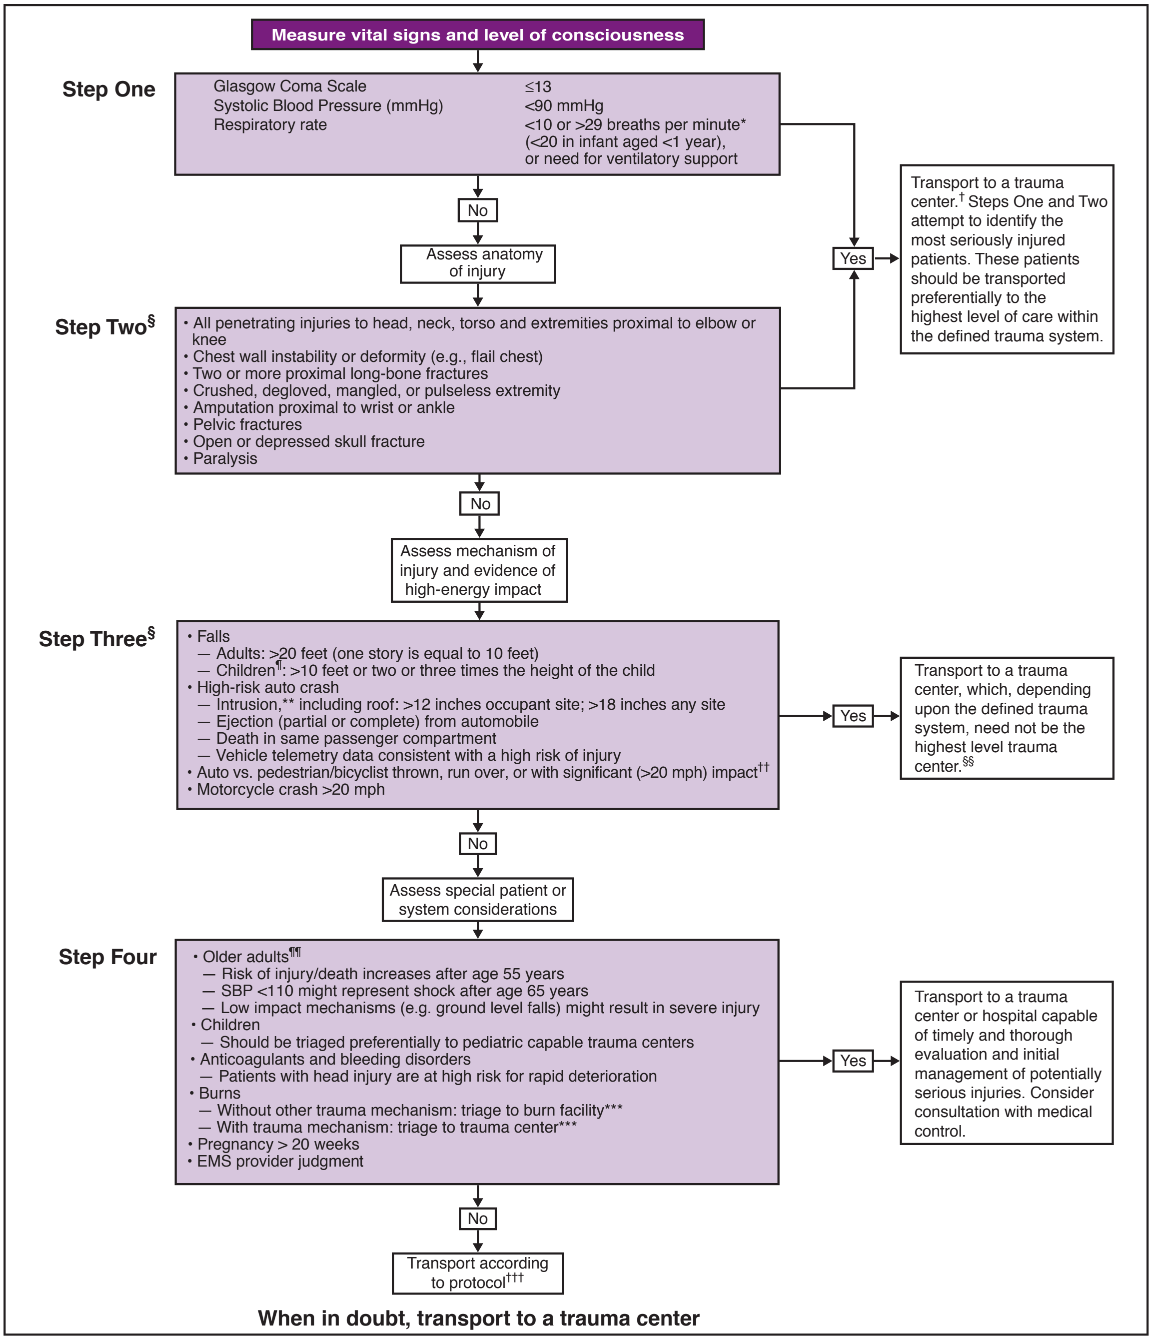
GCS, Glasgow Coma Scale; SBP, systolic blood pressure.

From Sasser SM, Hunt RC, Faul M, et al: Guidelines for field triage of injured patients: Recommendations of the National Expert Panel on Field Triage, 2011. MMWR Recomm Rep *61(RR-1):1-20, 2012 (Box 2, p. 8).*

Table 72-2	Children Requiring Pediatric Trauma Center Care

- Patients with serious injury to >1 organ or system
- Patients with 1-system injury who require critical care or monitoring in an intensive care unit
- Patients with signs of shock who require >1 transfusion
- Patients with fracture complicated by suspected neurovascular or compartment injury
- Patients with fracture of the axial skeleton
- Patients with ≥2 long-bone fractures
- Patients with potential replantation of an extremity
- Patients with suspected or actual spinal cord or column injury
- Patients with head injury with any 1 of the following:
  - Orbital or facial bone fracture
  - Cerebrospinal fluid leak
  - Altered state of consciousness
  - Changing neurologic signs
  - Open-head injury
  - Depressed skull fracture
  - Requiring intracranial pressure monitoring
  - Patients suspected of requiring ventilator support

Modified from Krug SE: The acutely ill or injured child. In Behrman RE, Kliegman RM, editors: Nelson essentials of pediatrics, *ed 4, Philadelphia, 2002, WB Saunders, p. 96.*



* The upper limit of respiratory rate in infants is >29 breaths per minute to maintain a higher level of overtriage for infants.

† Trauma centers are designated Level I-IV. A Level I center has the greatest amount of resources and personnel for care of the injured patient and provides regional leadership in education, research, and prevention programs. A Level II facility offers similar resources to a Level I facility, possibly differing only in continuous availability of certain subspecialties or sufficient prevention, education, and research activities for Level I designation; Level II facilities are not required to be resident or fellow education centers. A Level III center is capable of assessment, resuscitation, and emergency surgery, with severely injured patients being transferred to a Level I or II facility. A Level IV trauma center is capable of providing 24-hour physician coverage, resuscitation, and stabilization to injured patients before transfer to a facility that provides a higher level of trauma care.

§ Any injury noted in Step Two or mechanism identified in Step Three triggers a "yes" response.

¶ Age <15 years.

** Intrusion refers to interior compartment intrusion, as opposed to deformation which refers to exterior damage.

†† Includes pedestrians or bicyclists thrown or run over by a motor vehicle or those with estimated impact >20 mph with a motor vehicle.

§§ Local or regional protocols should be used to determine the most appropriate level of trauma center within the defined trauma system; need not be the highest-level trauma center.

¶¶ Age >55 years.

*** Patients with both burns and concomitant trauma for whom the burn injury poses the greatest risk for morbidity and mortality should be transferred to a burn center. If the nonburn trauma presents a greater immediate risk, the patient may be stabilized in a trauma center and then transferred to a burn center.

††† Patients who do not meet any of the triage criteria in Steps One through Four should be transported to the most appropriate medical facility as outlined in local EMS protocols.

Figure 72-1 Guidelines for Field Triage of Injured Patients—United States, 2011. *(From Guidelines for Field Triage of Injured Patients: recommendations of the National Expert Panel on Field Triage. MMWR 61:6, 2012.)*

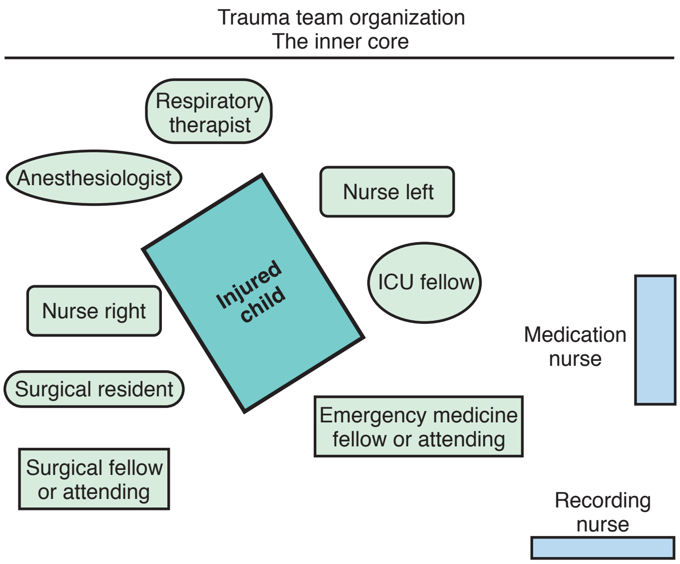


Figure 72-2 Members of the inner core of the trauma team at Children's National Medical Center (Washington, DC). Members of the outer core include a nursing administrator, a social worker, a radiology technician, a transport technician, and a security officer. ICU, intensive care unit.

Table 72-3 Pediatric Trauma Score

	CATEGORY		
Component	+2	+1	–1
Size	≥20 kg	10-12 kg	<10 kg
Airway	Normal	Maintainable	Unmaintainable
Systolic BP	≤90 mm Hg	90-50 mm Hg	<50 mm Hg
CNS	Awake	Obtunded/LOC	Coma/decerebrate
Open wound	None	Minor	Major/penetrating
Skeletal	None	Closed fracture	Open/multiple fractures
Sum total points			

Children with a Pediatric Trauma Score ≤6 are at increased risk of mortality as well as morbidity.

From Tepas JJ, Mollitt DL, Talbert JL, et al: The pediatric trauma score as a predictor of injury severity in the injured child. J Pediatr Surg *22:14–18, 1987, Table 1, p. 15.*

When the receiving ED is notified before the child's arrival, the trauma team should also be mobilized in advance. Each member has defined tasks. A senior surgeon (surgical coordinator) or, sometimes initially, an emergency physician leads the team. Team compositions vary somewhat from hospital to hospital; Figure 72-2 shows the model used at Children's National Medical Center (Washington, DC). Consultants, especially neurosurgeons and orthopedic surgeons, must be promptly available; the operating room staff should be alerted.

Physiologic status, anatomic locations, and/or mechanism of injury are used for field triage as well as to determine whether to activate the trauma team. More importance should be placed on physiologic compromise and less on mechanism of injury. Scoring scales such as the Abbreviated Injury Scale (AIS), Injury Severity Score (ISS), Pediatric Trauma Score (Table 72-3), and Revised Trauma Score use these parameters to predict patient outcome. The AIS and ISS are used together. First, the AIS is used to numerically score injuries—as 1 minor, 2 moderate, 3 serious, 4 severe, 5 critical, or 6 probably lethal—in each of 6 ISS body regions: head/neck, face, thorax, abdomen, extremity, and external. The ISS is the sum of the squares of the highest 3 AIS region scores.

PRIMARY SURVEY

During the primary survey, the physician quickly assesses and treats any life-threatening injuries. The principal causes of death shortly after trauma are airway obstruction, respiratory insufficiency, shock from hemorrhage, and central nervous system injury. The primary survey addresses the ABCDEs: Airway, Breathing, Circulation, neurologic Deficit, and Exposure of the patient and control of the Environment.

Airway/Cervical Spine

Optimizing oxygenation and ventilation, while protecting the cervical spine from potential further injury is of paramount importance. Initially, cervical spine injury should be suspected in any child sustaining multiple, blunt trauma. Children are at risk for such injuries because of their relatively large heads, which augment flexion–extension forces, and weak neck muscles, which predispose them to ligament injuries. To prevent additional spinal injury, the current standard is to immobilize the cervical (and thoracic and lumbar) spine in neutral position with a stiff collar, head blocks, tape or cloth placed across the forehead, torso, and thighs to restrain the child, and a rigid backboard.

Airway obstruction manifests as snoring, gurgling, hoarseness, stridor, and/or diminished breath sounds (even with apparently good respiratory effort). Children are more likely than adults to have airway obstruction because of their smaller oral and nasal cavities, proportionately larger tongues and greater amounts of tonsillar and adenoidal tissue, higher and more anterior glottic openings, and narrower larynxes and tracheas. Obstruction is common in patients with severe head injuries, owing in part to decreased muscle tone, which allows the tongue to fall posteriorly and occlude the airway. With trauma, obstruction can also result from fractures of the mandible or facial bones, secretions such as blood or vomitus, crush injuries of the larynx or trachea, or foreign body aspiration.

If it is necessary to open the airway, a jaw thrust **without head tilt** is recommended. This procedure minimizes cervical spine motion. In an unconscious child, an oropharyngeal airway can be inserted to prevent posterior displacement of the mandibular tissues. A semiconscious child will gag with an oropharyngeal airway but may tolerate a nasopharyngeal airway. *A nasopharyngeal airway is contraindicated when there is a possibility of a cribriform plate fracture*. If these maneuvers plus suctioning do not clear the airway, oral endotracheal intubation is indicated. When endotracheal intubation proves difficult, a laryngeal mask airway can be used as a temporary alternative. A laryngeal mask airway consists of a tube with an inflatable cuff that rests above the larynx and thus does not require placement of the tube into the trachea. Emergency cricothyrotomy is needed in <1% of trauma victims.

Breathing

The physician assesses breathing by counting the respiratory rate; visualizing chest wall motion for symmetry, expansion, and accessory muscle use; and auscultating breath sounds in both axillae. Continuous wave form capnography monitoring may also be used as an adjunct; however it is less reliable in patients with shock. In addition to looking visually for cyanosis, pulse oximetry is standard. If ventilation is inadequate, bag-valve-mask ventilation with 100% oxygen must be initiated immediately, followed by endotracheal intubation. End-expiratory carbon dioxide (CO_2) detectors help verify accurate tube placement.

Head trauma is the most common cause of respiratory insufficiency. An unconscious child with a severe head injury may have a variety of breathing abnormalities, including Cheyne-Stokes respirations, slow irregular breaths, and apnea.

Although less common than a pulmonary contusion, tension pneumothorax and massive hemothorax are immediately life-threatening (Tables 72-4 and 72-5). **Tension pneumothorax** occurs when air accumulates under pressure in the pleural space. The adjacent lung is compacted, the mediastinum is pushed toward the opposite hemithorax, and the heart, great vessels, and contralateral lung are compressed or

Table 72-4 Life-Threatening Chest Injuries

TENSION PNEUMOTHORAX
One-way valve leak from the lung parenchyma or tracheobronchial tree
Collapse with mediastinal and tracheal shift to the side opposite the leak
Compromises venous return and decreases ventilation of the other lung
Clinically, manifests as respiratory distress, unilateral absence of breath sounds, tracheal deviation, distended neck veins, tympany to percussion of the involved side, and cyanosis
Relieve first with needle aspiration, then with chest tube drainage
OPEN PNEUMOTHORAX (SUCKING CHEST WOUND)
Effect on ventilation depends on size
MAJOR FLAIL CHEST
Usually caused by blunt injury resulting in multiple rib fractures
Loss of bone stability of the thoracic cage
Major disruption of synchronous chest wall motion
Mechanical ventilation and positive end-expiratory pressure required
MASSIVE HEMOTHORAX
Must be drained with a large-bore tube
Initiate drainage only with concurrent vascular volume replacement
CARDIAC TAMPONADE
Beck Triad:
1. Decreased or muffled heart sounds
2. Distended neck veins from increased venous pressure
3. Hypotension with pulsus paradoxus (decreased pulse pressure during inspiration)
Must be drained

Modified from Krug SE: The acutely ill or injured child. In Behrman RE, Kliegman RM, editors: Nelson essentials of pediatrics, *ed 4, Philadelphia, 2002, WB Saunders, p. 97.*

kinked (see Chapter 411). Both ventilation and cardiac output are impaired. Characteristic findings include cyanosis, tachypnea, retractions, asymmetric chest rise, contralateral tracheal deviation, diminished breath sounds on the ipsilateral (more than contralateral) side, and signs of shock. Needle thoracentesis, followed by thoracostomy tube insertion, is diagnostic and lifesaving. **Hemothorax** results from injury to the intercostal vessels, lungs, heart, or great vessels. When ventilation is adequate, fluid resuscitation should begin before evacuation, because a large amount of blood may drain through the chest tube, resulting in shock.

Circulation

The most common type of shock in trauma is hypovolemic shock caused by hemorrhage. Signs of shock include tachycardia; weak pulse; delayed capillary refill; cool, mottled, pale skin; and altered mental status (see Chapter 70). Early in shock, blood pressure remains normal because of compensatory increases in heart rate and peripheral vascular resistance (Table 72-6). Some individuals can lose up to 30% of blood volume before blood pressure declines. *It is important to note that 25% of blood volume equals 20 mL/kg, which is only 200 mL in a 10 kg child.* Losses >40% of blood volume cause severe hypotension that, if prolonged, may become irreversible. Direct pressure should be applied to control external hemorrhage. Blind clamping of bleeding vessels, which risks damaging adjacent structures, is not advisable.

Cannulating a larger vein, such as an antecubital vein, is usually the quickest way to achieve intravenous access. A short, large-bore catheter offers less resistance to flow, allowing for more rapid fluid administration. Ideally, a second catheter should be placed within the first few minutes of resuscitation in a severely injured child. If intravenous access is crucial and not rapidly obtainable, an intraosseous catheter should be inserted; all medications and fluids can be administered intraosseously. Other alternatives are central venous access using the Seldinger technique (e.g., in the femoral vein) and, rarely, surgical

Table 72-5 Differential Diagnosis of Immediately Life-Threatening Cardiopulmonary Injuries

	TENSION PNEUMOTHORAX	MASSIVE HEMOTHORAX	CARDIAC TAMPONADE
Breath sounds	Ipsilaterally decreased more than contralaterally	Ipsilaterally decreased	Normal
Percussion note	Hyperresonant	Dull	Normal
Tracheal location	Contralaterally shifted	Midline or shifted	Midline
Neck veins	Distended	Flat	Distended
Heart tones	Normal	Normal	Muffled

Modified from Cooper A, Foltin GL: Thoracic trauma. In Barkin RM, editor: Pediatric emergency medicine, *ed 2, St. Louis, 1997, Mosby, p. 325.*

Table 72-6 Systemic Responses to Blood Loss in Pediatric Patients

SYSTEM	MILD BLOOD LOSS (<30%)	MODERATE BLOOD LOSS (30-45%)	SEVERE BLOOD LOSS (>45%)
Cardiovascular	Increased heart rate; weak, thready peripheral pulses; normal systolic blood pressure; normal pulse pressure	Markedly increased heart rate; weak, thready central pulses; peripheral pulses absent; low normal systolic blood pressure	Tachycardia followed by bradycardia; central pulses very weak or absent; peripheral pulses absent; hypotension; diastolic blood pressure may be undetectable
Central nervous system	Anxiety; irritability; confusion	Lethargy; dulled response to pain	Coma
Skin	Cool, mottled; capillary refill prolonged	Cyanotic; capillary refill markedly prolonged	Pale and cold
Urine output	Low to very low	Minimal	None

cutdown (e.g., in the saphenous vein). Ultrasonography can facilitate central venous catheter placement.

Aggressive, intravenous fluid resuscitation is essential early in shock to prevent further deterioration. Isotonic crystalloid solution, such as lactated Ringer injection or normal saline (20 mL/kg), should be infused rapidly. No consensus exists to support the routine use of colloid or hypertonic saline solution for shock (see Chapter 70). When necessary, repeated crystalloid boluses should be given. Most children are stabilized with administration of crystalloid solution alone. However, if the patient remains in shock after boluses totaling 40-60 mL/kg of crystalloid, then 10-15 mL/kg of cross-matched, packed red blood cells should be transfused. Although less desirable, type-specific or O-negative cells can be substituted pending availability of cross-matched blood. When shock persists despite these measures, surgery to stop internal hemorrhage is usually indicated.

Neurologic Deficit

Neurologic status is briefly assessed by determining the level of consciousness and evaluating pupil size and reactivity. The level of consciousness can be classified using the mnemonic AVPU: Alert, responsive to Verbal commands, responsive to Painful stimuli, or Unresponsive.

Head injuries account for at least 75% of pediatric blunt trauma deaths. Primary direct cerebral injury occurs within seconds of the event and is irreversible. Secondary injury is caused by subsequent anoxia or ischemia. The goal is to minimize secondary injury by ensuring adequate oxygenation, ventilation, and perfusion, and maintaining normal intracranial pressure (ICP). A child with severe neurologic impairment—i.e., with a Glasgow Coma Scale (GCS; see Table 67-3 in Chapter 67) score of 8 or less—should be intubated.

Signs of increased ICP, including progressive neurologic deterioration and evidence of transtentorial herniation, must be treated immediately (see Chapter 68). Hyperventilation lowers $Paco_2$, resulting in cerebral vasoconstriction, reduced cerebral blood flow, and decreased ICP. Brief hyperventilation remains an immediate option for patients with acute increases in ICP. Prophylactic hyperventilation or vigorous or prolonged hyperventilation is not recommended, because the consequent vasoconstriction may excessively decrease cerebral perfusion and oxygenation. Mannitol lowers ICP and may improve survival. Because mannitol acts via osmotic diuresis, it can exacerbate hypovolemia and must be used cautiously. Hypertonic saline may be a useful agent for control of increased ICP in patients with severe head injury and may possibly decrease mortality when compared with mannitol. Neurosurgical consultation is mandatory. If signs of increased ICP persist, the neurosurgeon must decide whether to operate emergently.

Exposure and Environmental Control

All clothing should be cut away to reveal any injuries. Cutting is quickest and minimizes unnecessary patient movement.

Children often arrive mildly hypothermic because of their higher body surface area : mass ratios. They can be warmed with use of radiant heat as well as heated blankets and intravenous fluids.

SECONDARY SURVEY

During the secondary survey, the physician completes a detailed, head-to-toe physical examination.

Head Trauma

A GCS or Pediatric GCS score (see Table 67-3 in Chapter 67) should be assigned to every child with significant head trauma. This scale assesses eye opening and motor and verbal responses. In the Pediatric GCS, the verbal score is modified for age. The GCS helps categorize neurologic disability, and serial measurements identify improvement or deterioration over time. Patients with low scores 6-24 hr after injuries have poorer prognoses.

In the ED, CT scanning of the head without a contrast agent has become standard to determine the type of injury in patients with concerning findings. Diffuse cerebral injury with edema is a common and serious finding on CT scan in severely brain-injured children. Focal evacuable hemorrhagic lesions (e.g., epidural hematoma) occur less commonly but may require immediate neurosurgical intervention (Fig. 72-3).

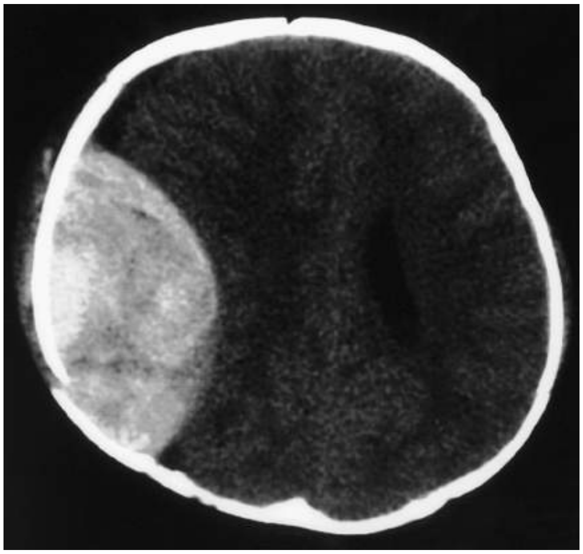

Figure 72-3 According to the history provided, the 7-month-old girl whose head CT scan is shown here did not wake up for her nightly feeding and began vomiting in the morning. The mother's boyfriend reported that the infant had fallen from a chair the previous day. The CT scan shows a large epidural hematoma on the right and marked shift of the midline from right to left. The right lateral ventricle is compressed as a result of the mass effect, and the left lateral ventricle is slightly prominent. The infant underwent emergency surgical evacuation of the epidural hematoma and recovered uneventfully. *(From O'Neill JA Jr:* Principles of pediatric surgery, *ed 2, St. Louis, 2003, Mosby, p. 191.)*

Monitoring of ICP should be strongly considered for children with severe brain injury, particularly for those with a GCS score of 8 or less and abnormal head CT findings (see Chapter 68). An advantage of an intraventricular catheter over an intraparenchymal device is that cerebrospinal fluid can be drained to treat acute increases in ICP. Hypoxia, hypercarbia, hypotension, and hyperthermia must be aggressively managed to prevent secondary brain injury. Cerebral perfusion pressure should be maintained >40 mm Hg at least (although some experts recommend an even higher minimum).

A child with a severe brain injury must be treated aggressively in the ED because it is very difficult to accurately predict long-term neurologic outcome. Compared with adults with similar injuries, children are thought to have better functional outcomes.

Cervical Spine Trauma

Cervical spine injuries occur in <3% of children with blunt trauma—with the risk being substantially higher in those with GCS scores ≤8—but they are associated with significant mortality and morbidity. Bony injuries occur mainly from C1 to C4 in children younger than 8 yr. In older children, they occur equally in the upper and lower cervical spine. The mortality rate is significantly higher in patients with upper cervical spine injuries. *Spinal cord injury without radiographic (vertebral body) abnormalities (SCIWORA) on plain films or CT may be present.* Patients with SCIWORA have neurologic symptoms, and spinal cord abnormalities are nearly always noted on MRI. Approximately 30% of all patients with cervical spine injuries have permanent neurologic deficits.

Evaluation begins with a detailed history and neurologic examination. Identifying the mechanism of injury helps in estimating the likelihood of a cervical spine injury. Both the patient and the paramedic should be asked whether any neurologic symptoms or signs, such as weakness or abnormal sensation, were present before arrival in the

Table 72-7 National Emergency X-Ray Utilization Study (NEXUS) to Rule Out Cervical Spine Injury Following Blunt Trauma

If none of the following are present, the patient is at very low risk for clinically significant cervical spine injury:
- Midline cervical tenderness
- Evidence of intoxication
- Altered level of alertness
- Focal neurologic deficit
- Distracting painful injury

Modified from Hoffman JR, Mower WR, Wolfson AB, et al: Validity of a set of clinical criteria to rule out injury to the cervical spine in patients with blunt trauma, N Engl J Med *343:94-99, 2000, and Viccellio P, Simon H, Pressman BD, et al: A prospective multicenter study of cervical spine injury in children,* Pediatrics *108(2):e20, 2001.*

Table 72-8 Indications for Operation in Thoracic Trauma

THORACOTOMY IMMEDIATELY OR SHORTLY AFTER INJURY
- Massive continuing pneumothorax or large air leak from tracheobronchial injury (cannot expand lung and ventilate)
- Cardiac tamponade
- Open pneumothorax
- Esophageal injury
- Aortic or other vascular injury
- Acute rupture of the diaphragm

DELAYED THORACOTOMY
- Chronic rupture of the diaphragm
- Clotted hemothorax
- Persistent chylothorax
- Traumatic intracardiac defects
- Evacuation of large foreign bodies
- Chronic atelectasis from traumatic bronchial stenosis

Modified from O'Neill JA Jr: Principles of pediatric surgery, *ed 2, St. Louis, 2003, Mosby, p. 157.*

ED. In a child with neurologic symptoms and normal findings on cervical spine plain radiographs and CT scan, SCIWORA must be considered.

Whenever the history, physical examination, or mechanism of injury suggests a cervical spine injury, radiographs should be obtained after initial resuscitation. The National Emergency X-Radiography Utilization Study (NEXUS) cervical spine rule helps identify low-risk patients who may not require radiographs (Table 72-7). The standard series of plain radiographs includes lateral, anteroposterior, and odontoid views. Some centers use cervical spine CT as the primary diagnostic tool, particularly in patients with abnormal GCS scores and/or significant injury mechanisms, recognizing that CT is more sensitive in detecting bony injury than plain radiographs. CT is also helpful if an odontoid fracture is suspected, because young children typically do not cooperate enough to obtain an "open-mouth" (odontoid) radiographic view. Use of cervical spine CT scan must be balanced with the knowledge that CT exposes thyroid tissue to 90-200 times the amount of radiation from plain films. MRI is indicated in a child with suspected SCIWORA and may also be useful in the evaluation of children who remain obtunded.

Rapid diagnosis of spinal cord injury is essential. Initiating high-dose intravenous methylprednisolone within 8 hr of spinal cord injury has been shown to improve motor outcome and remains standard therapy.

Thoracic Trauma

Pulmonary contusions occur frequently in young children with blunt chest trauma. A child's chest wall is relatively pliable; therefore, less force is absorbed by the rib cage, and more is transmitted to the lungs. Respiratory distress may be noted initially or may develop during the first 24 hr after injury.

Rib fractures result from significant external force. They are noted in patients with more severe injuries and are associated with a higher mortality rate. Flail chest, which is caused by multiple rib fractures, is rare in children. Indications for operative management in thoracic trauma are listed in Table 72-8. Table 72-5 shows the differential diagnosis of immediately life-threatening cardiopulmonary injuries.

Abdominal Trauma

Liver and spleen contusions, hematomas, and lacerations account for the majority of intra-abdominal injuries from blunt trauma. The kidneys, pancreas, and duodenum are relatively spared because of their retroperitoneal location. Pancreatic and duodenal injuries are more common after a bicycle handlebar impact or a direct blow to the abdomen (Table 72-9).

Although a thorough examination for intraabdominal injuries is essential, achieving it often proves difficult. Misleading findings can result from gastric distention after crying or in an uncooperative toddler. Calm reassurance, distraction, and gentle, persistent palpation help with the examination. Important findings include distention, bruises, and tenderness. Specific symptoms and signs give insight into

Table 72-9 Frequency of Abdominal Organ Injury by Injury Mechanism

BLUNT		PENETRATING	
Organ	**%**	**Organ**	**%**
Spleen	30	Gastrointestinal tract	70
Liver	28	Liver	27
Kidneys	28	Blood vessels	19
Gastrointestinal tract	14	Kidneys	10
Bladder/urethra/ureters	4	Spleen	9
Pancreas	3	Bladder/urethra/ureters	8
Blood vessels	3	Pancreas	6

Modified from O'Neill JA Jr: Principles of pediatric surgery, *ed 2, St. Louis, 2003, Mosby, p. 159.*

the mechanism of injury and the potential for particular injuries. Pain in the left shoulder may signify splenic trauma. A lap belt mark across the abdomen suggests a bowel or mesentery injury. The presence of certain other injuries, such as lumbar spinal fractures and femur fractures, increases the likelihood of intraabdominal injury.

An abdominal CT scan with intravenous contrast medium enhancement rapidly identifies structural and functional abnormalities and is the preferred study in a stable child. It has excellent sensitivity and specificity for splenic (Fig. 72-4), hepatic (Fig. 72-5), and renal injuries, but is not as sensitive for diaphragmatic, pancreatic, or intestinal injuries. Small amounts of free fluid or air or a mesenteric hematoma may be the only sign of an intestinal injury. Administration of an oral contrast agent is not routinely recommended for all abdominal CT scans, but it sometimes aids in identifying an intestinal, especially a duodenal, injury.

Although *focused assessment with sonography in trauma (FAST)* examination helps detect hemoperitoneum, the variably low sensitivity of this test in children suggests that it should not be used to exclude intraabdominal injury in patients with a high pretest probability for injury. Serial FAST exams over time may be used by skilled ultrasonographers to rule out injury in need of intervention. FAST is most useful in patients who have blunt trauma and are hemodynamically unstable or patients who require operative intervention for nonabdominal injuries, because in these cases the performance of a CT scan may not be feasible.

Nonoperative treatment has become standard for hemodynamically stable children with splenic, hepatic, and renal injuries from blunt

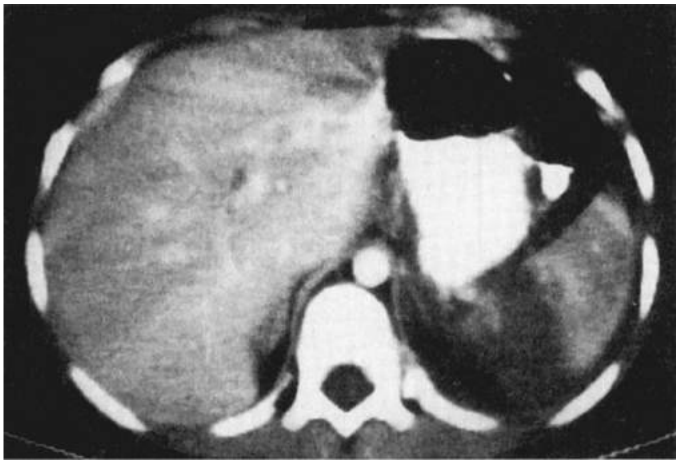

Figure 72-4 **CT scan with intravenous and gastrointestinal contrast enhancement shows an isolated splenic rupture that resulted from blunt trauma.** This injury responded to nonoperative management, as do most splenic injuries. *(From O'Neill JA Jr:* Principles of pediatric surgery, *ed 2, St. Louis, 2003, Mosby, p. 166.)*

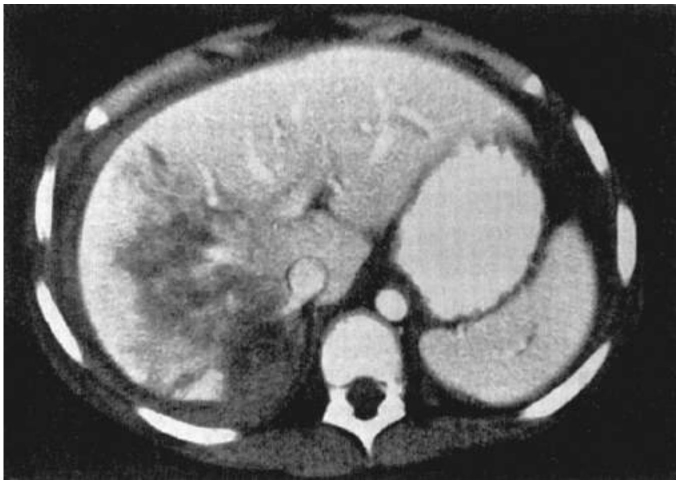

Figure 72-5 **CT scan performed after severe blunt injury of the abdomen shows a bursting injury of the liver.** The patient was stable, and no operative intervention was required. The decision to perform surgery should be based on the patient's physiologic stability. *(From O'Neill JA Jr:* Principles of pediatric surgery, *ed 2, St. Louis, 2003, Mosby, p. 168.)*

trauma. The majority of such children can be treated nonsurgically. In addition to avoiding perioperative complications, nonoperative treatment decreases the need for blood transfusions and shortens hospital stay. When laparotomy is indicated, splenic repair is preferable to splenectomy.

Pelvic Trauma

Pelvic fractures in children are much less common than in adults, occurring in approximately 4% of children with more severe blunt trauma. Pelvic fractures are typically caused by high forces (e.g., from high-speed motor vehicle crashes or pedestrian impacts) and are often associated with intraabdominal and/or vascular injuries. The pelvis itself forms a ring, and high-force impacts can lead to disruption of this ring. When the ring is disrupted in more than one location, such as the symphysis pubis and the sacroiliac joint, the ring can become unstable and displaced, potentially injuring large pelvic vessels and leading to massive blood loss. Catheter-directed embolization to control bleeding, performed by an interventional radiologist, may be required.

The pelvis should be assessed for stability by means of compression–distraction maneuvers. If instability is noted, immediate external fixation with a pelvis-stabilizing device or a sheet should be applied, and orthopedic consultation sought. A trauma patient with a potential pelvic fracture should receive an anteroposterior pelvic radiograph in the trauma bay, or a CT scan, if highly suspicious. Children without a high-risk clinical finding (i.e., GCS <14; abdominal pain or tenderness, pelvic tenderness, laceration, ecchymosis, or abrasion; positive urinalysis, or femur fracture) or a high-risk mechanism of injury (i.e., unrestrained motor vehicle collision, motor vehicle collision with ejection, motor vehicle collision rollover, auto vs. pedestrian, or auto vs. bicycle) are unlikely to have pelvic fractures, however.

Lower Genitourinary Trauma

The perineum should be inspected, and the stability of the bones of the pelvis assessed. Urethral injuries are more common in males. Findings suggestive of urethral injury include scrotal or labial ecchymoses, blood at the urethral meatus, gross hematuria, and a superiorly positioned prostate on rectal examination (in an adolescent male). Certain pelvic fractures also increase the risk for potential genitourinary injury. Any of these findings is a contraindication to urethral catheter insertion and warrants consultation with a urologist. Retrograde urethrocystogram and CT scan of the pelvis and abdomen are used to determine the extent of injury.

Extremity Trauma

Extremity fractures may initially be missed as clinicians attend to more life-threatening injuries. Thorough examination of the extremities is essential because extremity fractures are among the most frequently overlooked injuries in children with multiple trauma. All limbs should be inspected for deformity, swelling, and bruises; palpated for tenderness; and assessed for active and passive range of motion, sensory function, and perfusion.

Before radiographs are obtained, suspected fractures and dislocations should be immobilized, and an analgesic administered. Splinting a femur fracture helps alleviate pain and may decrease blood loss. An orthopedic surgeon should be consulted immediately to evaluate children with compartment syndrome, neurovascular compromise, open fracture, and most traumatic amputations.

Radiologic and Laboratory Evaluation

Some authorities recommend ordering multiple studies in the ED that include lateral cervical spine, anteroposterior chest, and anteroposterior pelvis radiographs; arterial blood gas analysis; serum lactate determinations; complete blood cell count; electrolyte measurements; blood glucose and blood urea nitrogen measurements; serum creatinine, amylase, and lipase determinations; liver function tests; prothrombin and partial thromboplastin time determinations; blood typing and cross-matching; and urinalysis. One benefit of standardizing the evaluation of patients with major trauma is that fewer decisions need to be made on an individual basis, possibly expediting ED management.

Some of these studies have prognostic importance. A large base deficit is associated with a higher mortality rate, and elevated lactate values correlate with poor prognosis.

There are limitations of standard tests. The lateral cervical spine radiograph can miss clinically significant injuries. Hemoglobin and hematocrit values provide baseline values in the ED, but they may not have yet equilibrated after a hemorrhage. Abnormal liver function test results or elevated serum amylase and lipase values may be noted in patients with significant abdominal trauma, but most patients with significant trauma to the abdomen already have clinical indications for CT scanning or surgery. The majority of previously healthy children have normal coagulation profiles; these may become abnormal after major head trauma. Although routine urinalysis or dipstick urine testing for blood has been recommended for children, other data suggest that this evaluation may be unnecessary in patients without gross hematuria, hypotension, or other associated abdominal injuries.

Table 72-10 Prediction Rule for Identification of Children at Very Low Risk of Clinically Important Brain Injuries After Head Trauma

Children <2 yr are at very low risk of clinically important traumatic brain injury if they have NONE of the following:	*Children 2-18 yr are at very low risk of clinically important traumatic brain injury if they have NONE of the following:*
Severe mechanism of injury History of LOC >5 seconds GCS ≤14 or other signs of altered mental status Not acting normally per parent Palpable skull fracture Occipital/parietal/temporal scalp hematoma	Severe mechanism of injury History of LOC History of vomiting GCS ≤14 or other signs of altered mental status Severe headache in the ED Signs of basilar skull fracture

Modified from Kuppermann N, Holmes JF, Dayan PS, et al: Identification of children at very low risk of clinically-important brain injuries after head trauma: a prospective cohort study, Lancet *374:1160–1170, 2009.*

Table 72-11 Prediction Rule for Identification of Children at Very Low Risk of Clinically Important Intraabdominal Injuries After Blunt Trauma

If none of the following are present, the patient is at low risk for clinically significant intraabdominal injury:
GCS <14
Vomiting
Evidence of thoracic wall trauma
Decreased breath sounds
Evidence of abdominal wall trauma or seatbelt sign
Abdominal pain
Abdominal tenderness

Modified from Holmes JF, Lillis K, Monroe D, et al: Identifying children at very low risk of clinically important blunt abdominal injuries, Ann Emerg Med *62(2): 107–116e2, 2013.*
